That the analysis and labeling of dietary carbohydrates, for whatever purpose, be based on the chemical divisions recommended. Additional groupings such as polyols, resistant starch, non-digestible oligosaccharides and dietary fiber can be used, provided the included components are clearly defined.

In line with this, methods for the measurement of free sugars, starch, NSP and, more recently, short-chain carbohydrates including inulin have been developed.\(^6\)–\(^11\)

The Englyst procedure for the measurement of dietary fiber as NSP has evolved from the principles laid down by McCance and Widdowson and later by Southgate.\(^10\)–\(^12\) The procedure involves enzymatic hydrolysis of starch, precipitation of NSP in ethanol, acid hydrolysis of the NSP and measurement of the released constituent sugars by GLC, HPLC or colorimetry. Values for total, soluble and insoluble NSP may be obtained using any of the end-point techniques. The detailed information obtained from the chromatographic methods, which identify and quantify the individual constituent sugars, is particularly useful in studies of the relation between intakes of NSP and health; values for the constituent NSP sugars have been published for a wide range of foods.\(^13\)–\(^14\) The spectrum of the constituent sugars is characteristic for various types of plant NSP and may indicate the origin of the NSP measured and the physiological effects. The values for wholemeal bread and wholemeal wheat products are characterized by high levels of insoluble NSP in the form of cellulose (measured as insoluble NSP glucose (\(\text{Glc}\))) and arabinoxylans. Wholemeal wheat NSP are fermented slowly and incompletely, and exert a considerable effect on fecal bulk. White bread contains only 30\% as much NSP as wholemeal bread, and these NSP are largely soluble and have little effect on fecal bulk. Oats contain a greater proportion of soluble NSP compared with wheat products, and the main fraction is a \(\beta\)-glucan, which is measured as soluble NSP Glc. This is associated with a greater effect on cholesterol metabolism, which is in agreement with the health claims for oat products. Fruit and vegetables have high levels of soluble fiber, and the main fraction in these foods is pectin, which is measured as soluble NSP uronic acids (\(\text{Uac}\)). In general, cereal products contain more xylose (\(\text{Xyl}\)) than arabinose (\(\text{Ara}\)), while fruits and vegetables contain less Xyl than Ara, which is measured mainly in the soluble fraction. High values for \(\text{Uac}\) indicate a diet rich in fruits and vegetables. When the detailed information on the constituent sugars is not required, values for total,

\(a\) A diet rich in fruit, vegetables and whole-grain cereal products as recommended in national dietary guidelines.
soluble and insoluble dietary fiber may be obtained by
the more rapid colorimetric end-point procedure. The
colorimetric version can be completed within 8 working
hours, and it is suitable for food labeling and for quality
control. The Englyst procedure for the measurement of
dietary fiber as NSP has been thoroughly tested in large
international collaborative trials. Values for dietary
fiber measured as NSP by this technique are used in the
McCance and Widdowson UK food tables.

The nutritional classification of plant NSP is given in
Table 1.

2 HISTORICAL BACKGROUND AND THE
DEFINITION OF DIETARY FIBER

The link between the ingestion of unprocessed foods and
good health is chronicled as far back as Hippocrates (4th
century BC), who recommended the eating of wholemeal
bread for its "salutary effects upon the bowels". The term
dietary fiber was first used by Hipsley, and the dietary fiber
hypothesis, which was put forward by Cleave, Burkitt
and Trowell more than 2000 years after Hippocrates,
was related to the health benefits consequent upon the
ingestion of a diet rich in unrefined plant foods and
was specifically related to the plant cell wall. The
plant cell wall encapsulates and thus controls the release
of nutrients, including free sugars and starch, from the
plant tissue and thereby influences the glycemic response.
This ability to influence digestion and absorption, and
thus the physiological effects of other nutrients, was
seen at an early stage to be an important property of
dietary fiber. The other main properties associated
with dietary fiber were its ability to increase fecal bulk and
reduce transit time, and its ability to adsorb and eliminate
cholesterol and potentially toxic substances, thus affecting
large gut physiology and health. On the basis of these
original concepts, any material characterized as dietary
fiber should have the physicochemical characteristics of
the cell-wall material in plant foods. No type of starch
(including that escaping digestion in the human small
intestine), inulin or any of the naturally occurring or
semisynthetic mono-, di- or oligosaccharides that are not
digested and absorbed in the human small intestine has
the inherent properties of plant cell-wall material, and
none should be included in the definition or measurement
of dietary fiber. The structural integrity of plant cell
walls may hinder the access of digestive enzymes and
cause starch to escape digestion, but there is no reason
to classify that starch, or starch escaping digestion
in the small intestine for whatever reason, as dietary
fiber.

Dietary fiber and starch are chemically distinct com-
ponents, and Trowell made it clear that the definitions
proposed earlier were not intended to include starch
when he stated in his comment on definitions that,"derived from plant cell walls and not digested by
human alimentary enzymes, starch was excluded from
all these definitions and was never named at that time
or subsequently as a constituent of dietary fiber". He
concluded, “At the present time there is considerable
international agreement concerning the principal con-
stituents of dietary fiber. They are all polysaccharides,
mainly cellulose, hemicelluloses and pectic substances,
conveniently designated nonstarch polysaccharides”. In
1987 it was proposed by Englyst et al. that dietary fiber
should be defined and measured, for the purpose of food
labeling, as NSP.

Naturally high-fiber diets are low in free sugars, salt
and fat, and provide a good source of a range of nutrients,
including vitamins, minerals and antioxidants. All the
properties of a high-fiber diet, including those related
to the structural properties such as the encapsulation of
nutrients within plant cell walls, have been implicated in
the protection from a variety of diseases.

It is clear that any definition used as the basis for
measurement of dietary fiber must provide values that
serve as a reliable marker for a high-fiber diet if they are
to be meaningful in terms of the evidence that exists in
support of the dietary fiber hypothesis.

3 APPLICATIONS AND HEALTH
IMPLICATIONS

3.1 Scope and Field of Application

Dietary fiber defined and measured as NSP, as described
by Englyst et al., is in keeping with the original concept
of dietary fiber. Measurement of NSP provides a reliable
index of plant cell-wall material and gives the analyst a
clear objective.

The methods have been used successfully for the anal-
ysis of a very wide range of foods. The information
obtained by the GLC and HPLC procedures is valuable
for interpreting the results of physiological and epidemi-
ological studies where disease may be related to the type of
dietary fiber. When detailed information is not required,
however, values for NSP can be obtained by colorimetry.
In comparative studies of a wide range of food prod-
ucts, good agreement has been demonstrated between
the GLC, HPLC and colorimetric versions of the Englyst
procedure.

NSP are not affected by normal food processing, so the
amounts of fiber in processed foods and mixed diets can
be calculated simply from knowledge of the amount in the
raw product, although possible losses to the boiling water
must be taken into account. This independence of the
method from food processing makes values for dietary fiber measured as NSP suitable for food labeling and easy to defend.

3.2 Food Tables

In addition to the FAO/WHO, the compilers and the users of food tables and databases in general are currently requesting specific measurements of dietary carbohydrates that will allow total carbohydrates to be calculated as the sum of the parts rather than, as has been done in the past, calculating carbohydrates ‘by difference’. The calculation is not possible, however, when techniques are used that yield values for a mixture of components, and many of the current ‘fiber’ techniques include noncarbohydrate components of the sample material.

Different countries have chosen methods that include different components and therefore yield different values for fiber. The material measured as “fiber” by nonspecific gravimetric procedures may be a mixture of NSP, starch and noncarbohydrate components in unspecified proportions that may vary as the result of food processing; such values are impossible to interpret in chemical terms and cannot be used in energy calculations. Like other values, dietary fiber must be based on the measurement of chemically identified components.

3.3 Food Labeling

The purpose of food labeling for dietary fiber is to help the consumer in choosing the high-fiber diet recommended in nutritional guidelines.

NSP represent the principal component (approximately 90%) of plant cell walls, and their measurement provides a good measure of endogenous plant cell-wall material for most plant foods. NSP values thus provide a reliable marker for the high-fiber diet embodied in the dietary fiber hypothesis and recommended in national dietary guidelines.

Fiber is included as a carbohydrate for nutritional labeling in some countries, while in others it is listed separately. We suggest that when dietary fiber is measured as NSP, it is properly listed under carbohydrate for nutritional labeling purposes.

3.4 Physiological Studies and Health Implications

The digestion of plant polysaccharides has been studied in some detail using this technique, and all the NSP have been demonstrated to reach the human large intestine where they may be fermented at different rates and to different extents. The gases carbon dioxide, hydrogen and, in about 50% of people, methane, and the short-chain fatty acids propionate, acetate and butyrate in various proportions are the major end-products of fermentation by the large gut microbiota. The gases are absorbed and lost via the lungs or passed as flatus. The short-chain fatty acids are absorbed and represent a source of energy, e.g. butyrate is absorbed and used as the main source of energy for the colonic epithelia.

Although NSP are not digested and absorbed in the human small intestine, their presence can influence the rate and extent of digestion and absorption of other dietary carbohydrates. Starch and sugars trapped within whole plant cells or a dense food matrix may be digested and absorbed more slowly because access of the hydrolytic enzymes is physically hindered (this is discussed in more detail in the article Starch Analysis in Food).

4 METHODS AND PRINCIPLES OF MEASUREMENT

The Englyst procedure measures dietary fiber as NSP, using enzymatic chemical methods, and has evolved from the principles laid down by Southgate in 1969. Starch is completely removed enzymatically and NSP are measured as the sum of the constituent sugars released by acid hydrolysis. The sugars may be measured by GLC or HPLC to obtain values for individual monosaccharides or a single value for total sugars may be obtained by colorimetry. Values may be obtained for total, soluble and insoluble NSP, and a small modification allows cellulose to be measured separately.

The Englyst procedure allows the measurement of total, soluble and insoluble NSP in plant food products within an 8 h working day using the colorimetric end-point, or within 1.5 working days with the chromatographic procedures. Preparation of the hydrolyzate for

DIETARY FIBER ANALYSIS AS NON-STARCH POLYSACCHARIDES

5

analysis is virtually a single-tube procedure and no special skill or equipment is needed for the colorimetric version.

The procedure as described here provides the following options. (1) GLC procedure: measures NSP as the sum of neutral sugars obtained by GLC and Uac measured separately. (2) HPLC procedure: measures NSP as the sum of neutral sugars and Uac. (3) Colorimetric procedure: measures NSP as reducing sugars. (4) Colorimetric procedure with separate measurement of Uac. The principle is set out in Table 2.

4.1 Apparatus and Reagents

High-purity reagents and distilled, deionized water, or water of equivalent purity, should be used throughout the method.

4.1.1 Reagents Common to Gas–Liquid Chromatography, Colorimetric and/or High-performance Liquid Chromatography Procedures

All sugars used for standards should be dried to constant mass under reduced pressure with phosphorus pentoxide before use.

**Acidified Ethanol** Absolute and 85% (v/v). Add 1 mL of 5 mol L\(^{-1}\) hydrochloric acid per liter of ethanol.

**Benzoic Acid, Saturated** Prepare a saturated solution of benzoic acid at room temperature. Add 0.5 g of benzoic acid per 100 mL of water; some benzoic acid should remain undissolved after overnight stirring. The saturated solution is stable at room temperature for long periods.

**Dimethylphenol Solution** Dissolve 0.1 g of 3,5-dimethylphenol in 100 mL of glacial acetic acid.

**Dimethyl Sulfoxide**

**Enzyme Solution I** Take 2.5 mL of heat-stable amylase (EC 3.2.1.1: Termamyl; Englyst Carbohydrate Services, Cat. No. 7367-723), make to 200 mL with pre-equilibrated sodium acetate buffer, mix and keep it in a 50°C water-bath. Prepare the solution immediately before use.

**Enzyme Solution II** Take 1.2 g of pancreatin (Sigma, Cat. No. P1500) in a 50-mL tube, add 12 mL of water, vortex-mix initially and then mix for 10 min with a magnetic stirrer. Vortex-mix again, then centrifuge at low speed for 10 min. Take 10 mL of the (cloudy) supernatant, add 2.5 mL of pullulanase (EC 3.2.1.41: Promozyme; Englyst Carbohydrate Services, Cat. No. 7367-727) and vortex-mix. Prepare the solution immediately before use and keep it at room temperature.

**Glass Balls** 2.5–3.5 mm diameter (Merck, Cat. No. 332124G).

**Sand** Acid-washed, 50–100 mesh (Merck, Cat. No. 330945E).

**Sodium Acetate Buffer** 0.1 mol L\(^{-1}\), pH 5.2. Dissolve 13.6 g of sodium acetate trihydrate and make up to 1 L with water. Adjust to pH 5.2 with 0.1 mol L\(^{-1}\) acetic acid. To stabilize and activate enzymes, add 4 mL of 1 mol L\(^{-1}\) calcium chloride to 1 L of buffer.

**Sodium Chloride–Boric Acid Solution** Dissolve 2 g of sodium chloride and 3 g of boric acid in 100 mL of water.

**Sodium Phosphate Buffer** 0.2 mol L\(^{-1}\), pH 7. Adjust 0.2 mol L\(^{-1}\) \(\text{Na}_2\text{HPO}_4\) to pH 7 with 0.2 mol L\(^{-1}\) \(\text{NaH}_2\text{PO}_4\). To stabilize and activate enzymes, add 4 mL of 1 mol L\(^{-1}\) calcium chloride to 1 L of buffer.

**Sulfuric Acid** 12 mol L\(^{-1}\) (Merck, Cat. No. 19321 6Y).

**Sulfuric Acid** 2 mol L\(^{-1}\). Add 5 mL of 12 mol L\(^{-1}\) sulfuric acid to 25 mL of water. Allow to cool to room temperature before use.

**Sulfuric Acid** 2.4 mol L\(^{-1}\). Add 5 mL of 12 mol L\(^{-1}\) sulfuric acid to 20 mL of water.

4.1.2 Reagents Used Only in the Gas–Liquid Chromatography Procedure

**Acetic Anhydride**

**Ammonium–Sodium Tetrahydroborate Solution** A solution of 6 mol L\(^{-1}\) ammonium hydroxide, containing 200 mg mL\(^{-1}\) of sodium tetrahydroborate (NaBH\(_4\)). Prepare immediately before use.

**Bromophenol Blue Solution** 0.4 g L\(^{-1}\) (Merck, Cat. No. 21006 4K).

**gas–Liquid Chromatography Internal Standard Solution** 1 mg mL\(^{-1}\). Weigh, to the nearest 1 mg, 500 mg of allose. Dissolve in water, add 250 mL of saturated benzoic acid and make up to 500 mL with water to give a 1 mg mL\(^{-1}\) solution. The solution is stable at room temperature for several months.

**Glacial Acetic Acid**

**gas–Liquid Chromatography Stock Sugar Mixture** Weigh, to the nearest 1 mg, 0.52 g of rhamnose (Rha), 0.48 g of fucose (Fuc), 4.75 g of Ara, 4.45 g of Xyl, 2.3 g of mannose (Man), 2.82 g of galactose (Gal), 9.4 g of Glc
and 2.79 g of galacturonic acid (GalA) (or 3.05 g of GalA monohydrate). Dissolve together in water, add 500 mL of saturated benzoic acid and make up to 1 L with water. The solution is stable at room temperature for several months.

1-Methylimidazole

4.1.3 Reagents Used Only in the High-performance Liquid Chromatography Procedure

High-performance Liquid Chromatography Neutral Sugars Internal Standard Solution Weigh, to the nearest 1 mg, 10 000 mg of deoxygalactose. Add 10 mg of thiomersal (C₂H₅HgSC₆H₄COONa) as preservative and make up to 1 L with water.

High-performance Liquid Chromatography Neutral Sugars Stock Sugar Mixture Weigh, to the nearest 1 mg, 0.52 g of Rha, 0.48 g of Fuc, 4.75 g of Ara, 4.45 g of Xyl, 2.3 g of Man, 2.82 g of Gal and 9.4 g of Glc. Dissolve together in water, add 10 mg of thiomersal as preservative and make up to 1 L with water. Store at 4°C.

High-performance Liquid Chromatography Uronic Acids Internal Standard Solution Weigh, to the nearest 1 mg, 0.0454 g of mannuronic acid lactone. Dissolve in water, add 1 mg of thiomersal as preservative and make up to 100 mL with water. Store at 4°C.

High-performance Liquid Chromatography Uronic Acids Stock Sugar Mixture Weigh, to the nearest 1 mg, 0.0930 g of GalA (or 0.102 g of GalA monohydrate) and 0.0233 g of glucuronic acid (GlcA). Dissolve together in 2 mol L⁻¹ sulfuric acid and make up to 100 mL with 2 mol L⁻¹ sulfuric acid. Store at 4°C.

Pectinase Solution Add 9 volumes of water to 1 volume of pectinase (EC 3.2.1.15; Englyst Carbohydrate Services, Cat. No. 7367-726).

4.2 Sample Preparation

All samples must be finely divided (to pass a 0.5-mm mesh) so that representative subsamples may be taken. Foods with a low water content (<10 g per 100 g of sample) may be milled, and foods with a higher water content may be homogenized wet or milled after freeze-drying. Analysis of three sub-samples, A, B and C, allows separate values to be obtained directly for total NSP, insoluble NSP and cellulose, respectively. Soluble NSP is determined as the difference between total and insoluble NSP. Portions A and B are treated identically throughout the procedure, except in steps 3 and 4. The third portion, C, is needed only if a separate value for cellulose is required; carry it through steps 1, 2 and 3 of the procedure then go to step 5.2.

Step 1.1 Weigh, to the nearest 1 mg, between 50 and 1000 mg, depending on the water and NSP content of the sample (to give not more than 300 mg of dry matter, e.g. 300 mg is adequate for most dried foods but smaller amounts should be used for bran and purified fiber preparations) into 50–60-mL screw-topped glass tubes. Add 300 (±20) mg of acid-washed sand and approximately 15 glass balls to each. If the sample is dry (85–100 g of dry matter per 100 g of sample) or contains less than 10 g of fat per 100 g of sample, proceed to step 2; otherwise, go to step 1.2. All analyses should be done in duplicate.

Step 1.2 Add 40 mL of acetone, cap the tubes and mix several times over 30 min. Centrifuge at 1000 g for 10 min to obtain a clear supernatant and remove as much
of the supernatant liquid as possible without disturbing the residue. Vortex-mix vigorously to ensure that the residue is dispersed thinly around the bottom 5 cm of the tube. Place the rack of tubes in a pan of water at 75 °C in a fume-cupboard. Remove the tubes singly and vortex-mix vigorously at frequent intervals until the tubes and residues are dry.

4.3 Isolation and Hydrolysis of Nonstarch Polysaccharides

4.3.1 Dispersion and Enzymatic Hydrolysis

Pre-equilibrate sufficient acetate buffer at 50 °C (8 mL required per sample).

**Step 2.1** Add 2 mL of DMSO to the dry sample, cap the tube and immediately mix the contents using a vortex-mixer, treating each tube in turn. It is essential that all the sample is wetted and no material is encapsulated or adhering to the tube wall before proceeding. When DMSO has been added to all the tubes, vortex-mix three or four times during 5 min. Vortex-mix and immediately place two tubes in a boiling water-bath. Remove after 20 s, vortex-mix and immediately replace the tubes in the bath. Repeat this for subsequent pairs of tubes until all the tubes are in the bath, then leave them for 30 min from that time. During this period, prepare enzyme solutions I and II (see section 4.1; the volumes given are suitable for 24 samples).

**Step 2.2** Remove one tube at a time, vortex-mix, uncap and immediately add 8 mL of enzyme solution I (kept at 50 °C), cap the tube, vortex-mix thoroughly, ensuring that no material adheres to the tube wall, and replace it in the boiling water-bath. Leave the tubes there for 10 min, timed from the last addition of enzyme. Transfer the rack of tubes to the 50 °C water-bath. After 3 min, add 0.5 mL of enzyme solution II to each tube and mix the contents thoroughly to aid distribution of the enzyme throughout the sample. Replace the tubes in the 50 °C water-bath and leave them there for 30 min. Mix the contents of each tube continuously or after 10, 20 and 30 min. Transfer the rack of tubes to the boiling water-bath and leave them there for 10 min.

4.3.2 Precipitation and Washing of the Residue for Measurement of Total Nonstarch Polysaccharides

Only sample portion A is given this treatment.

**Step 3.1** Cool the samples by placing in ice–water. Add 0.15 mL of 5 mol L⁻¹ hydrochloric acid and vortex-mix thoroughly two or three times during 5 min with samples being replaced in the ice–water. Add 40 mL of acidified absolute ethanol and mix well by repeated inversion, then leave in ice–water for 30 min. Centrifuge at 1500 g for 10 min to obtain a clear supernatant liquid. Remove as much of the supernatant liquid as possible, without disturbing the residue, and discard it.

**Step 3.2** Add approximately 10 mL of acidified 85% ethanol to the residue and vortex-mix. Make up to 50 mL with acidified 85% ethanol and mix thoroughly by repeated inversion. Centrifuge and remove the supernatant liquid as above. Repeat this stage using 50 mL of absolute ethanol.

**Step 3.3** Add 30 mL of acetone to the residue and vortex-mix thoroughly to form a suspension. Centrifuge and remove the supernatant liquid as described in step 3.1.

**Step 3.4** Place the rack of tubes in a pan of water at 75 °C in a fume-cupboard or a TurboVap (Zymark) at 65 °C. Remove the tubes singly and vortex-mix vigorously at frequent intervals, to ensure that the residue in each tube is finely divided, until each tube and residue appears dry. Place the rack of tubes in a fan oven at 80 °C for 10 min to remove any last traces of acetone. It is essential that the residues and tubes are completely free of acetone.

4.3.3 Extraction and Washing of the Residue for Measurement of Insoluble Nonstarch Polysaccharides

Only sample portion B is given this treatment.

**Step 4.1** After the treatment with enzymes in step 2, add 40 mL of sodium phosphate buffer. Place the capped tubes in a boiling water-bath for 30 min. Mix continuously or a minimum of three times during this period. Remove the tubes and equilibrate to room temperature in water. Centrifuge and remove the supernatant liquid as described in step 3.1.

**Step 4.2** Add approximately 10 mL of water and vortex-mix. Make up to approximately 50 mL with water and mix well by repeated inversion. Centrifuge and remove the supernatant liquid as described in step 3.1. Repeat this stage using 50 mL of absolute ethanol. Proceed as described for steps 3.3 and 3.4.

4.3.4 Acid Hydrolysis of the Residue from Enzymatic Digestion

Only sample portion A is given this treatment.

**Step 5.1** Add 5 mL of 12 mol L⁻¹ sulfuric acid to one tube and immediately vortex-mix vigorously: ensure that all the material is wetted. Repeat this for each tube in turn. Once the acid has been added to all the tubes, vortex-mix again and place all the tubes in a water-bath at 35 °C.
Leave the tubes at 35 °C for 30 min with vigorous vortex-mixing after 5, 10 and 20 min to disperse the cellulose. Add 25 mL of water rapidly and vortex-mix. Place into a boiling water-bath and leave for 1 h, timed from when boiling recommences; mix after 10 min. Cool the tubes in tap water.

**Step 5.2**  A modification allowing the separate measurement of cellulose and noncellulosic polysaccharides (NCP). To portion C, after steps 1–3, add 30 mL of 2 mol L⁻¹ sulfuric acid, and mix. Place in a boiling water-bath and leave for 1 h, timed from when boiling recommences, stirring continuously or after 10 min. The value for cellulose is obtained as the difference between total NSP and cellulose.

### 4.3.5 Breaks in the Procedure

The procedure may be halted at either of the following stages: (1) after precipitation, washing and drying the starch-free residue in steps 3 and 4; the residue may be stored for long periods; or (2) after the hydrolysis with starch-free residue in steps 3 and 4; the residue may be stored for long periods; or (2) after the hydrolysis with sulfuric acid. Treat 2 × 1.0 mL of the cooled hydrolyzates from step 5; the hydrolyzate may be kept at 4 °C for 48 h.

### 4.4 Determination of Constituent Sugars by Gas–Liquid Chromatography

This assay includes the measurement of neutral sugars by GLC and the separate measurement of Uac by colorimetry.

#### 4.4.1 Measurement of Neutral Nonstarch Polysaccharide Constituents by Gas–Liquid Chromatography

For preparation of the standard sugar mixture, mix 1.0 mL of the GLC stock sugar solution and 5 mL of 2.4 mol L⁻¹ sulfuric acid. Treat 2 × 1.0 mL of this standard sugar mixture for calibration in parallel with the hydrolyzates from step 5 of the procedure. Prepare the alditol acetate derivatives for chromatography as follows. Add 0.50 mL of GLC internal standard (IS) (1 mg mL⁻¹ allose) to 1.0 mL of the cooled hydrolyzates from step 5 and to 2 × 1 mL of the standard sugar mixture; vortex-mix. Place the tubes in ice–water, add 0.4 mL of 12 mol L⁻¹ ammonium solution and vortex-mix. Test that the solution is alkaline (add a little more ammonium solution if necessary but replace the ammonium solution if more than 0.1 mL extra is required), then add approximately 5 μL of the antifoam agent octan-2-ol and 0.1 mL of the ammonium–sodium borohydride solution and vortex-mix. Leave the tubes in a heating block or in a water-bath at 40 °C for 30 min, then remove and add 0.2 mL of glacial acetic acid and mix again. Transfer 0.5 mL into a 30-mL glass tube and add 0.5 mL of 1-methylimidazole and 5 mL of acetic anhydride. Vortex-mix, then leave the tubes for 10 min for the reaction to proceed (the reaction is exothermic and the tubes will become hot). Add 0.9 mL of absolute ethanol, vortex-mix and leave for 5 min. Add 10 mL of water, vortex-mix and leave for 5 min. Add 0.5 mL of bromophenol blue solution. Place the tubes in ice–water and add 5 mL of 7.5 mol L⁻¹ potassium hydroxide; a few minutes later, add a further 5 mL of 7.5 mol L⁻¹ potassium hydroxide, cap the tubes and mix by inversion. Leave until the separation into two phases is complete (10–15 min) or centrifuge for a few minutes. Draw part of the upper phase into the tip of an automatic pipette; if any of the blue lower phase is included, allow it to separate, then run it out of the tip before transferring a portion of the upper phase alone to a small (autoinjector) vial. Inject 0.5–1 μL of the alditol acetate derivatives.

#### 4.4.2 Gas–Liquid Chromatography Conditions

The following conditions are used: injector temperature, 275 °C; column temperature, 220 °C; detector temperature, 275 °C; carrier gas, helium; flow-rate, 8 mL min⁻¹. Under these conditions, a GLC system fitted with flame ionization detector, autoinjector and computing integrator, using a Supelco SP-2330 wide-bore capillary column (30 m × 0.75 mm ID) or a Supelco SP-2380 wide-bore capillary column (30 m × 0.53 mm ID) will allow accurate determination of the individual sugars in the GLC standard sugar mixture within 8 min. Carry out conventional GLC measurement of the neutral sugars. At the beginning of each batch of analyses, equilibrate with the isothermal elution conditions for at least 1 h. Do several calibration runs to check that the response factors are reproducible.

#### 4.4.3 Calibration

Calibration ratios are shown in Table 3 for the combination of the GLC standard sugar mixture and GLC IS.

**Table 3** Calibration details for GLC

(allose). The “Actual” column shows the amount of each sugar in the mixture and the “Apparent” column shows the values to be used for calibration taking into account the recovery of NSP constituents. The “Calibration ratio” column gives the ratio of sugars to the IS after the addition of allose to the standard sugar mixture as described in the text. (The experimental evidence for the recovery values has been published and is discussed in detail in section 6.3.)

4.4.4 Calculation of Neutral Sugars

The amount of each individual sugar (expressed as grams of polysaccharide per 100 g of sample) is calculated according to Equation (1):

\[
\text{Sugar} = \frac{A(t) \times W(i) \times 100 \times R(f) \times 0.89}{A(i) \times W(t)}
\]

where \(A(t)\) and \(A(i)\) are the peak areas of the sample and the IS, respectively, \(W(i)\) is the weight (in milligrams here 15: total hydrolyzate 30 mL \times 0.5 mg allose) of the IS; \(W(t)\) is the weight (in milligrams) of the sample, \(R(f)\) is the response factor for individual sugars obtained from the calibration run with the sugar mixture and IS (allose) treated in parallel with the samples and 0.89 is the factor for converting experimentally determined values for monosaccharides to polysaccharides.

4.4.5 Measurement of Uronic Acids by Colorimetry

Prepare the standard solutions as follows. The GLC standard sugar mixture in 2 mol L\(^{-1}\) sulfuric acid contains, for the purpose of calibration, 500 µg mL\(^{-1}\) of GalA. To prepare the uronic acid standard solutions, transfer 0.5, 2.0 and 3.0 mL of this sugar mixture into separate tubes and make up to 10 mL with 2 mol L\(^{-1}\) sulfuric acid to give standards of 25, 100 and 150 µg mL\(^{-1}\) of GalA.

Place in separate tubes (40–50-mL capacity) 0.3 mL of blank solution (2 mol L\(^{-1}\) sulfuric acid), 0.3 mL of each of the standard solutions and 0.3 mL of the sample hydrolyzates, diluted if necessary (with 2 mol L\(^{-1}\) sulfuric acid) to contain no more than 150 µg mL\(^{-1}\) of Uac (e.g. no dilution for flour, 1:2 for bran, 1:5 for most fruits and vegetables). Add 0.3 mL of sodium chloride–boric acid solution and mix. Add 5 mL of concentrated sulfuric acid and vortex-mix immediately. Place the tubes in a heating block at 70°C for 40 min. Remove the tubes and cool to room temperature in water (the tubes may be kept in the water for up to 1 h). Add 0.2 mL of dimethylphenol solution and vortex-mix immediately. After 15 min measure the absorbance at 400 and 450 nm in the spectrophotometer against the blank solution. The timing for measurement of the absorbance of standards and samples should be identical. In practice, this is achieved by adding the color reagent at 1-min intervals. Subtract the absorbance reading at 400 nm from that at 450 nm, to correct for interference from hexoses. A straight line should be obtained if the differences in absorbance for the standards are plotted against concentration. Only the 100 µg mL\(^{-1}\) standard is required for routine analysis, and it may be kept at 5°C for several weeks.

4.4.6 Calculation of Uronic Acids

The amount of Uac (expressed as grams of polysaccharide per 100 g of sample) is calculated according to Equation (2):

\[
\text{Uac} = \frac{A(t) \times V(t) \times D \times C \times 100 \times 0.91}{A(s) \times W(t)}
\]

where \(A(t)\) is the difference in absorbance of the sample solution, \(V(t)\) is the total volume of sample solution (in milliliters, here 30), \(D\) is the dilution of the sample solution, \(C\) is the concentration of the standard (here 0.1 mg mL\(^{-1}\)), \(A(s)\) is the difference in absorbance of the 100 µg mL\(^{-1}\) standard, \(W(t)\) is the weight (in milligrams) of the sample and 0.91 is the factor for converting experimentally determined values for monosaccharides to polysaccharides.

4.4.7 Calculation of Nonstarch Polysaccharides

The amounts of total, soluble and insoluble NSP (in grams per 100 g of sample) are calculated as follows:

- Total NSP = neutral sugars calculated for portion A + Uac calculated for portion A
- Insoluble NSP = neutral sugars calculated for portion B + Uac calculated for portion B
- Soluble NSP = Total NSP – Insoluble NSP

It is recommended that a sample is taken for determination of the dry matter as the loss in weight after overnight incubation at 104°C. Results may then be expressed as grams of polysaccharides per 100 g of dry matter.

4.4.8 Breaks in the Gas–Liquid Chromatography Procedure

The procedure may be halted at either of the following stages: (1) after acidification of the reduced samples (see section 4.4); the samples may be stored at room temperature for 2–3 days; (2) the acid hydrolyzate from step 5 may be kept at 5°C for several weeks before the measurement of Uac.
4.5 Determination of Constituent Sugars by High-performance Liquid Chromatography

This assay includes dilution of one subsample of the hydrolyzate and direct measurement of the neutral sugars, and the separate measurement of Uac in a second subsample of the hydrolyzate subjected to treatment with pectinase.

4.5.1 Measurement of Neutral Sugars by High-performance Liquid Chromatography

For preparation of the HPLC standard sugar mixture, mix 1.0 mL of the HPLC stock sugar mixture and 5 mL of 2.4 mol L\(^{-1}\) sulfuric acid. Treat 2 × 0.15 mL of this standard sugar mixture for calibration of HPLC in parallel with the hydrolyzates from step 5 of the procedure.

To 0.15 mL of hydrolyzate or the HPLC standard sugar mixture add 5 mL of the HPLC neutral sugars IS solution (deoxygalactose) and mix well. Inject 25 µL for analysis.

4.5.2 High-performance Liquid Chromatography Conditions

A Dionex Model PAD 2 detector may be used with the following pulse potentials and durations: \(E_1 = 0.05\ \text{V} \quad (t_1 = 300\ \text{ms})\); \(E_2 = 0.60\ \text{V} \quad (t_2 = 120\ \text{ms})\); \(E_3 = -0.60\ \text{V} \quad (t_3 = 60\ \text{ms})\). The response time is 1 s and the detector output is set at 1000 nA.

A Dionex AG-5 guard column, an inert high-pressure valve and a CarboPac PA-1 column are placed in series. The AG-5 column and inert high-pressure valve are used to retain and bypass sulfate ions around the analytical column. Elute with the following: 23% (v/v) solution 1 (20 mmol L\(^{-1}\) NaOH) from 0 to 3.5 min; a gradient from 23% to 1% (v/v) solution 1 from 3.5 to 4.5 min; and 1% (v/v) solution 1 from 4.5 to 30 min at a flow rate of 1 mL min\(^{-1}\). Re-equilibrate with the starting conditions for at least 6 min between runs. Add 300 mmol L\(^{-1}\) NaOH at a flow-rate of 0.5 mL min\(^{-1}\) to the column effluent before the pulsed amperometric detection (PAD) cell to minimize baseline drift and increase the analytical signal. Saturate the eluent with helium (Dionex Eluent De-gas module) to minimize CO\(_2\) absorption. Under the conditions described here, sulfate ions are retained for 80 s on the AG5 guard column and column switching (via the inert high-pressure valve) is applied after 60 s to prevent sulfate ions from reaching the analytical column. Sulfate ions are purged from the guard column within 19 min, well within the total run time. To regenerate the PA-1 column at the end of the chromatographic run, wash with 100 mmol L\(^{-1}\) NaOH–600 mmol L\(^{-1}\) sodium acetate for 1 h at a flow-rate of 1 mL min\(^{-1}\). Then, wash with 1 mol L\(^{-1}\) NaOH (1 mL min\(^{-1}\)) for 1 h but, to avoid contamination of the internal reference solution, do not allow this solution to pass through the detector.

The calibration ratios are shown in Table 4 for the combination of the standard sugar mixture and deoxygalactose, the HPLC IS: the “Actual” column shows the amount of each sugar in the mixture, and the “Apparent” column shows the values to be used for calibration taking into account the recovery of NSP constituents.

The amount of each individual sugar (in grams per 100 g of sample) is calculated according to Equation (3):

\[
\text{Sugar} = \frac{A(t) \times W(i) \times 100 \times R(f)}{A(i) \times W(t)} \times 0.89
\]

where \(A(t)\) and \(A(i)\) are the peak areas of the sample and the HPLC IS, respectively, \(W(i)\) is the weight of the IS if added to the whole sample (in milligrams, here 25), \(W(t)\) is the weight of the sample (in milligrams), \(R(f)\) is the response factor for individual sugars obtained from a calibration run with the sugar mixture treated in parallel with the samples and 0.89 is the factor for converting experimentally determined values for monosaccharides to polysaccharides. It is recommended that a sample is taken for analysis of the dry matter as the loss in weight after overnight incubation at 104 °C. Results may then be expressed as grams of polysaccharides per 100 g of dry matter.

4.5.3 Measurement of Uronic Acids by High-performance Liquid Chromatography

To 0.5 mL of hydrolyzate or calibration mixture, add 0.5 mL of the HPLC Uac IS solution (mannuronic acid lactone), 0.5 mL of DMG solution (8 g per 100 mL) and 2.1 mL of 1 mol L\(^{-1}\) NaOH. After vortex-mixing, the pH must be between pH 3.5 and 4.0 (if the pH is not correct, prepare fresh DMG solution and repeat). Add 0.1 mL of pectinase solution, vortex-mix and place the tubes in a water-bath at 50°C for 20 min. Cool the tubes, remove 0.5 mL, add 0.1 mL of phenol red indicator solution (1 mg mL\(^{-1}\)) and add sufficient (approximately

and mannuronic acid is achieved isocratically within a graphic column. Baseline separation of GalA, (GlcA) and mannuronic acid is achieved isocratically within 13 min using 25% solution 2 (100 mmol L\(^{-1}\) NaOH, 600 mmol L\(^{-1}\) sodium acetate) and 75% water at a flow-rate of 1.0 mL min\(^{-1}\).

Use the following ratios for the calibration mixture for the calculation of the response factors: 0.5 for GalA, 0.125 for GlcA and 0.25 for mannuronic acid, to take into account losses during hydrolysis. The values for the calculation of response factors take into account 7% loss of both GalA and GlcA, and the hydrolysis of mannuronic acid lactone to mannuronic acid.

The amount of Uac (in grams per 100 g of sample) is calculated according to Equation (4):

\[
Uac = \frac{A(t) \times W(t) \times 100 \times R(t) \times 0.91}{A(i) \times W(t)}
\]  

(4)

where \(A(t)\) and \(A(i)\) are the peak areas of the sample and the IS, respectively, \(W(i)\) and \(W(t)\) are the weight of the IS (in milligrams; here 15) and the weight of the sample (in milligrams), respectively, \(R(t)\) is the response factor for individual Uac obtained from the calibration mixture and 0.91 is the factor for converting the experimentally determined values for monosaccharides to polysaccharides.

4.6 Determination of Constituent Sugars by Colorimetry

4.6.1 Preparation of the Standard Sugar Mixture

Take 0.5 mL of the colorimetry stock sugar mixture into a glass tube, add 2.5 mL of 2.4 mol L\(^{-1}\) sulfuric acid and mix to give 3 mL of 3 mg mL\(^{-1}\) color sugars standard solution in 2 mol L\(^{-1}\) sulfuric acid. The colorimetric reaction is linear up to 3 mg mL\(^{-1}\) sugar. The absorbance of the test samples should not exceed that of the standard.

4.6.2 Measurement of Total Reducing Sugars

Place all the tubes together into a briskly boiling water-bath for 5 min. Remove the rack of tubes and cool to room temperature in water. Add 10 mL of water (at room temperature) and mix well by inversion (do not use a vortex-mixer at this stage). Measure the absorbance at 530 nm against blank 2.

Note: sample blanks may be prepared by diluting the hydrolyzates as described above, replacing the color reagent with water, and reading the absorbance against water. Alternatively, and more conveniently, the absorbance of the undiluted hydrolyzate can be measured against water and the value divided by 24.4 (the dilution of the hydrolyzate after addition of the color reagent and water). The absorbance of the test sample is then calculated by subtracting this value. When the hydrolyzate is colorless and the NSP content is more than 5%, the sample blank is not required.

4.6.3 Calculation of Nonstarch Polysaccharides

The amount of total NSP (portion A) and of insoluble NSP (portion B), in grams of polysaccharide per 100 g of sample, is calculated according to Equation (5):

\[
NSP = \frac{A(t) \times V(t) \times D \times F \times C \times 100 \times 0.89}{A(s) \times W(t)}
\]  

(5)

where \(A(t)\) is the absorbance of the sample solution (minus the absorbance of the hydrolyzate blank if measured), \(V(t)\) is the total volume of the sample solution (in milliliters, here 30), \(D\) is the dilution of the sample solution \((D = 1\) if no dilution), \(F\) is the factor correcting the difference between the composition of monosaccharides in the standard sugar mixture and that in NSP of various types of plant foods [for the calculation of NSP in cereals (except oats) \(F = 0.95\), in fruit and non-starchy vegetables \(F = 1.05\) and in starchy vegetables, oat products and unknown samples \(F = 1\); using the standard sugar mixture as specified and these factors makes corrections for the 2–4% hydrolytic losses], \(C\) is the concentration (in mg mL\(^{-1}\) sugars) of the standard, \(A(s)\) is the absorbance of the standard, \(W(t)\) is the weight (in milligrams) of sample taken for analysis and 0.89 is the factor for converting experimentally determined monosaccharides to polysaccharides. The amount of soluble NSP is calculated as the difference between total NSP and insoluble NSP. It is recommended that a sample is taken for analysis of the dry matter as the loss in weight after overnight incubation at 104 °C. Results may then be expressed as grams of polysaccharides per 100 g of dry matter.
4.6.4 Correction Based on Separate Measurement of Uronic Acids

When a sample, e.g., pectin, has a high content of Uac, a more accurate value for NSP may be obtained if Uac are measured separately. The color standard sugar mixture contains 12.5% (w/v) Uac, and it has been determined (data not shown) that this leads to a 17% underestimation of NSP when the sample contains only Uac (using \( F = 1 \)). Correction for the underestimation is straightforward if a separate value for Uac is obtained (see above). If the sample contains 12.5% monomeric Uac, the color standard sugar mixture is entirely appropriate and no correction is required; otherwise, the correction required is an increment or decrement to the NSP value obtained by colorimetry equivalent to 17% of the uronic acid content that is in excess of or less than 12.5% of the sample, respectively.

The percentage of the NSP value to be corrected for is the difference (\( \Delta \)) between the value for Uac (\( Z \); expressed as a percentage of the NSP value, \( X \)) and 12.5, and is calculated according to Equation (6):

\[
\Delta = \left( \frac{Z}{X} \times 100 \right) - 12.5 \tag{6}
\]

and the correction factor \( Y \) is calculated using Equation (7):

\[
Y = 0.17 \left( \frac{X}{100} \times \Delta \right) \tag{7}
\]

which may be reduced to 0.17Z - 0.021X, and then the value for total NSP after correction is \( X + Y \).

4.6.5 Breaks in the Colorimetry Procedure

The procedure may be halted at either of the following stages: (1) after precipitation, washing and drying the starch-free residue (see step 3.4); the residue may be stored for long periods. (2) After the hydrolysis with 2 mol L\(^{-1}\) sulfuric acid; the hydrolyzate may be kept at 4°C for 48 hours.

5 QUALITY CONTROL AND TROUBLESHOOTING

Two kits are available from Englyst Carbohydrate Services to help ensure that accurate analytical results are obtained. The kit for the colorimetric procedure contains color reagent and a second kit contains a solution of allose as IS for the GLC procedure. Both kits contain the required enzymes, sugar solutions and reference materials and are rigorously tested in-house. The use of all four reference materials as suggested below may be used as part of a complete quality control procedure.

Reference sample 1 (white flour) This sample is used to check the efficiency of the starch hydrolysis and washing steps where there is small amounts of NSP in the presence of large amounts of starch.

Reference sample 2 (haricot bean) This sample contains all the constituent sugars of NSP and is used to check the efficiency of the starch hydrolysis and washing steps for samples that may cause handling problems, such as aggregation.

Reference sample 3 (high-amylose starch resistant to \( \alpha \)-amylose) This sample is taken through the entire procedure for total NSP and is used to check the efficiency of the starch hydrolysis and washing steps.

Reference sample 4 (cellulose) This sample is subjected to direct acid hydrolysis only and is used to check the acid hydrolysis steps.

5.1 Troubleshooting for the Common Hydrolysis Steps

1. Variation between replicate analyses may be due to inaccurate pipetting (test/calibrate dispensers by weighing replicates of water) or to incomplete removal of acetone in step 3.4.

2. If values for Glc are too high for samples of known composition and/or variable for replicates, this may be due to incomplete wetting of sample with DMSO in step 2.1. Mix vigorously immediately after addition of DMSO.

3. If values for Glc and Uac for samples of known composition are too low and/or are variable for replicates, this may be due to incomplete hydrolysis of samples with 12 mol L\(^{-1}\) sulfuric acid in step 5. Vortex-mix vigorously before and after addition of sulfuric acid and at intervals during the incubation.

5.2 Troubleshooting for the Gas–Liquid Chromatography Procedure

1. Extra peaks on the chromatogram may be due to incomplete reduction of monosaccharides. Ensure an alkaline pH before adding NaBH\(_4\). Replace old NaBH\(_4\); do not compensate for loss of activity by adding more NaBH\(_4\).

2. Variation between replicate analyses may be caused by nonreproducible pipetting of the IS or hydrolyzates. Test/calibrate dispensers by weighing 1 mL replicates of water.

3. If the response factors are not reproducible, this may be due to inaccurate pipetting of the sugar mixture and/or IS. Test/calibrate dispensers by weighing replicates of water.
5.3 Troubleshooting for the High-performance Liquid Chromatography Procedure

If retention times vary during chromatography, regenerate the analytical columns as described in section 4.5.

5.4 Troubleshooting for the Colorimetry Procedure

1. Variation between replicate analyses may be due to inaccurate pipetting (test/calibrate dispensers by weighing replicates of water) or to incomplete removal of acetone in step 3.4.
2. If no color is produced for standards and/or samples, this may be due to an error in the preparation of the sulfuric acid or sodium hydroxide solutions. Make new reagents. Test that the pH of the solution is between 7 and 8 before adding the color reagent solution.

6 METHOD DEVELOPMENT

6.1 Isolation of Nonstarch Polysaccharides

Isolation of NSP from starch and free sugars is achieved by dispersal and enzymatic hydrolysis of starch and subsequent precipitation of NSP. The enzymatic hydrolysis of starch with amylase, pullulanase and amyloglucosidase was initially achieved with an overnight incubation. The introduction of glass balls and sand to prevent agglutination and the use of a heat-stable amylase has reduced the length of incubation to less than 1 h. Oligosaccharides may be linked to polysaccharides by noncovalent bonds, such as calcium bridges forming complexes that are insoluble in 80% ethanol at pH 5.2 as used in earlier versions of the NSP procedure. Some free GaLA is insoluble in 80% ethanol in the presence of sodium acetate buffer (0.1 mol L\(^{-1}\), pH 5.2). Acidifying the 80% ethanol to pH 2 solubilizes all free GaLA and prevents coprecipitation of oligosaccharides, thus avoiding their artifactual inclusion in the measurement of NSP. Values obtained for the total NSP content of a polysaccharide mixture (duplicate analysis on four different occasions) were 91.2% (±2.8%) (w/w) and 91.9% (±2.1%) (w/w) when the precipitation in ethanol was done at pH 5.2 and 2, respectively.

6.2 Optimization of Nonstarch Polysaccharide Hydrolysis Conditions

Cellulose and some uronic acid-containing materials require dispersal in 12 mol L\(^{-1}\) sulfuric acid before hydrolysis is possible. In the Englyst procedure as it was described in 1982, NSP were completely dispersed and hydrolyzed by treatment with 12 mol L\(^{-1}\) sulfuric acid for 1 h at 35 °C, followed by treatment with 1 mol L\(^{-1}\) sulfuric acid for 2 h at 100 °C. Subsequently, it was shown that the second step could be completed within 1 h using 2 mol L\(^{-1}\) sulfuric acid. The 1 h of treatment with 12 mol L\(^{-1}\) sulfuric acid was incorporated because it was found that some samples aggregate during the drying with acetone, hindering the access of the 12 mol L\(^{-1}\) sulfuric acid and requiring prolonged treatment to ensure complete dispersion and hydrolysis. It has been shown that dispersal in 12 mol L\(^{-1}\) sulfuric acid is complete within 10 min if samples are in powder form. In 1994, sand and glass balls were incorporated into the procedure to prevent aggregation and to ensure that samples are finely divided after the drying procedure. With this modification, the treatment with 12 mol L\(^{-1}\) sulfuric acid was reduced to 30 min without affecting the results.

As a test for completeness of depolymerization, HPLC with PAD was used to detect any oligosaccharides remaining in solution after the acid hydrolysis steps. No residual oligomers were detected after hydrolysis of cellulose and other noncellulosic neutral sugar-containing NSP, indicating complete hydrolysis. Oligosaccharides were found, however, after hydrolysis of uronic acid-containing polymers, such as pectin, indicating incomplete depolymerization. This incomplete hydrolysis is not important if the uronic acid content is to be determined by the modified Scott procedure as used in the GLC analysis of NSP, because this method measures both free Uac and uronic acid polymers in solution. When using the colorimetric or HPLC procedures, however, prolonged treatment (3 h) with 2 mol L\(^{-1}\) sulfuric acid is required to obtain maximal values. Such a treatment is time-consuming and results in further undesirable losses.

Treatment with pectinase after adjustment of the pH of the hydrolyzate to between 3.5 and 4 was introduced and this resulted in complete recovery of Uac within 20 min, with the added benefit of no hydrolysis loss. These modifications have improved the analysis of NSP by the colorimetric procedure and allowed measurement of the Uac by HPLC, which had not been previously described.

6.3 Response Factors in the Chromatographic Assays

In the Englyst procedure, NSP are hydrolyzed by treatment with 12 mol L\(^{-1}\) sulfuric acid for 30 min at 35 °C, followed by treatment with 2 mol L\(^{-1}\) sulfuric acid for 1 h at 100 °C. The treatment with 12 mol L\(^{-1}\) sulfuric acid is essential for dispersal but results in extensive sulfation of the monosaccharides, requiring subsequent hydrolysis with dilute acid at high temperature. This, in turn, causes some destruction of the monosaccharides released. The conditions chosen for hydrolysis are therefore necessarily a compromise between adequate release, desulfation and

destruction of the monosaccharides. These parameters have been extensively investigated and a full report is given elsewhere.\(^{11}\) Table 5 shows a summary of the results and shows how the composition of the sugar calibration mixture used in the GLC and HPLC procedures (used for calibration of response factors) takes into account the incomplete recoveries.

6.4 Factors Affecting the Reducing Sugar Assay

A colorimetric procedure was introduced by Englyst and Hudson as a faster, more convenient alternative to the GLC procedure for obtaining values for total NSP.\(^{36}\) This colorimetric technique, however, consistently gave values that were slightly higher for cereal products and marginally lower for some fruits and vegetables that contained large amounts of Uac than the values obtained by GLC.\(^{15}\) The procedure was subsequently modified in 1994, incorporating four changes.\(^{10}\)

Treatment with pectinase was introduced to complete the hydrolysis of the uronic acid-containing material and this has improved the recovery for fruits and vegetables. Advanced Maillard Reaction Products (MRP), such as 5-hydroxymethylfurfural and 2-furaldehyde, formed during cooking, have reducing aldehyde groups that react with the color reagent. MRP exhibit a time-dependent increase in absorbance, whereas virtually maximum values are obtained for the NSP constituent monosaccharides at 5 min. The absorbance values for 5-hydroxymethylfurfural at 5 min are only 30% of those obtained at 15 min, the incubation time in the original procedure. The time of reaction with the color reagent has been reduced to 5 min, which has minimized the interference from products formed during food processing.

Mineral ions have been reported to increase the intensity of the color formed upon heating dinitrosalicylic acid with reducing sugars. We showed that mineral ions from the salts of potassium, calcium, phosphorus, sodium, iron, zinc, copper and manganese and traces of cobalt, aluminum and molybdenum were soluble in acidified 80% (v/v) ethanol at pH 2, and the use of acidified ethanol has completely removed this source of interference.\(^{10}\)

The fourth modification was the introduction of factors to take into account the different composition of the NSP of fruits, vegetables, cereal products, starchy legumes and oat products: 43 vegetables, 40 fruits, 52 cereal products (other than oats) and 17 starchy legume and oat product samples were analyzed by the GLC procedure. On the basis of the monosaccharide composition and knowledge of the color yields of individual monosaccharides, we determined that factors of 1.05 for fruits and vegetables and 0.95 for cereals are appropriate. No correction is required for starchy legumes or oat products when using the color sugar mixture described here (section 4.6).

In summary, sources of potential interference in the measurement of NSP have been identified and eliminated, making the NSP procedure more accurate and robust. Virtually identical values for NSP have subsequently been obtained for all samples measured by the GLC and the colorimetric end-points and the improvements have been reflected by reduced interlaboratory variation as observed in the EU Community Bureau of Reference (BCR) detailed methods study (see section 7.3).

7 METHOD VALIDATION

7.1 Comparison of the Colorimetric, Gas–Liquid Chromatography and High-performance Liquid Chromatography Assays

Three end-point techniques are available as alternatives to obtain values for NSP. The chromatographic
procedures yield detailed information about the composition of the dietary fiber but require more sophisticated equipment. We have demonstrated that the GLC and HPLC procedures give identical values for both neutral sugars\(^{37,38}\) and Uac.\(^{37} \)\(^{38}\) The colorimetric procedure has been demonstrated in interlaboratory studies to give values for total, soluble and insoluble NSP that are identical with values obtained by the chromatographic procedures. The colorimetric assay is ideally suited for food labeling purposes or where values for individual constituent sugars are not required.

### 7.2 International Collaborative Trials

The Englyst procedure has been the subject of a series of international collaborative trials organized by the UK Ministry of Agriculture, Fisheries and Food (MAFF).\(^{15}\) This has culminated in the publication of the GLC and colorimetry techniques as MAFF Approved Methods\(^{39,40}\).

In the MAFF IV study, 37 laboratories from 11 countries took part to compare the accuracy and precision of the Englyst GLC and colorimetric procedures and the Association of Official Analytical Chemists (AOAC) Prosky gravimetric method. All methods performed reasonably well for both repeatability and reproducibility but differences were seen in the results. The Prosky procedure gave values that were, on average, 19% higher than those obtained by the Englyst procedure, and the reasons are explained in detail in section 8. The results in Table 6 show an overall summary of the results obtained by the Englyst GLC, Englyst colorimetry and Prosky procedures.

### 7.3 Certification of Reference Materials

As the result of a large international trial of methodology, following rigorous study of stability of the test materials, five BCR certified reference materials (CRMs) are available for the Englyst GLC and colorimetry NSP procedures: \(^{16}\) (1) dried haricot bean powder, CRM 514; (2) dried carrot powder, CRM 515; (3) dried apple powder, CRM 516; (4) full fat soya flour, CRM 517; and (5) dried powdered bran breakfast cereal, CRM 518. These CRMs can be used to check the performance of the analytical method and as quality control of analytical measurements for nutritional labeling.

### 8 COMPARISON WITH THE PROSKY PROCEDURE

The UK MAFF commissioned a study in 1996 to determine the reason for the differences in values obtained for dietary fiber by the widely used Prosky procedure and by the Englyst NSP procedures, the two major contenders for fiber labeling for foods.\(^{41}\)

Analytical values used with intake values to calculate the amounts of “fiber” provided in the UK diet and the results are given in Table 7.

Equal “fiber” intakes are obtained for the Meat products group, as expected, and only small differences are observed for the Fruit products and Nuts groups. However, the intakes calculated with the Prosky values for the other seven food groups are, on average, 37% higher than those calculated using the NSP values, ranging from 20% (Green vegetables) to 85% (Other vegetables) higher for single food groups.

The results of the study showed:

- MRP produced by heating various combinations of carbohydrates and proteins are measured as dietary fiber by the Prosky procedure.
- Some starch escapes digestion in vivo because it is inaccessible to enzymes (resistant starch types 1 and 2).

see the article Starch Analysis in Food), but this starch is made available to enzymatic hydrolysis in vitro by the milling and heating steps in the Prosky procedure, and therefore is not included in Prosky fiber values. In contrast, starch that is digestible in foods that are normally eaten hot may retrograde during the cooling of samples for analysis to a form that is not digestible by the enzymes used in the Prosky procedure and is hence included in the measurement.

- Fat, even at levels below that requiring extraction according to the protocol, can be included in the Prosky values.

- Organic acids may be included in the Prosky values, and the proportion included is increased in the presence of calcium.

The stated aim of the Prosky procedure is to measure the sum of indigestible polysaccharides and lignin but this is not achieved, since the procedure does not measure inulin or all resistant starch. Further, the Prosky procedure includes artifacts, such as MRP, and highly variable amounts (up to 40% of the material measured) of unidentified material. This, together with the conceptual difference in the definition of dietary fiber, is the reason for the difference between values obtained by the Englyst procedure and those obtained by the Prosky procedure. Note that because, in general, the Prosky procedure does include NSP, Prosky values will tend to be equal to or greater than values for NSP, and the Prosky value may be further increased by food processing.

Electrophoresis is based on the differential migration of charged components in an electric field. Until recently, gel electrophoresis and particularly sodium dodecyl sulfate (SDS) polyacrylamide gel electrophoresis (PAGE) were the main electrophoretic techniques used in food analysis. Recently, capillary electrophoresis (CE) has become widely adopted for the monitoring of many food components.

Such rapid development is due to several factors, but especially to speed and versatility. Most often separation can be performed in a few minutes with minimal sample preparation. A new method can be started by filling the capillary with the proper buffer, and new modular instruments can be rapidly fitted with the appropriate detector. Various CE procedures have been developed since the introduction of this technique. Capillary zone electrophoresis (CZE), the basic CE method, consists of a capillary tubing of fused silica with a diameter of 50–150 µm. The tube is filled with a buffer and subjected to an electric field, and under these conditions the positive charged species migrate toward the cathode at a rate determined by their mass-to-charge ratios. However, a net movement of the buffer toward the cathode, electroosmotic flow (EOF), is generated within the tube by the ionized capillary wall silanol groups. As a result, all the molecules present in the buffer proceed toward the cathode, the neutral molecules migrate as a single group, and each negative species moves toward the cathode at a rate determined by the difference between the EOF and its anodic attraction. The other main CE techniques are micellar electrokinetic chromatography (MEKC), where an anionic surfactant is added to the buffer to form negatively charged micelles, isotachophoresis (ITP), in which the sample is sandwiched between electrolytes of high and low mobility and the analytes migrate in order of decreasing mobility, and isoelectric focusing (IEF), which is one of the main techniques used in protein gel electrophoresis: amphoteric electrolytes are allowed to migrate in a capillary where they form a pH gradient. In such a gradient, proteins move until they reach their isoelectric point (pI). Many detection techniques have been applied to CE, including direct and indirect ultraviolet (UV) absorption, fluorescence, electrochemical detection and even mass spectrometry (MS).

Most food components can be examined with these techniques, particularly proteins, ions, organic acids, sugars and various plant chemicals.

1 INTRODUCTION

In order to maintain quality, food destined for human consumption is submitted to a considerable number of analyses from the raw ingredient to the final product. The analytical data must be able to assess the authenticity of the food material but should also reveal the possible addition of adulterants. Most of the chemical and physical methods that were developed have been applied to food analysis as it can be seen in the Official Methods of Analysis of the Association of Official Analytical Chemists (AOAC) International. Hundreds of methods can be found using techniques from simple titration to complex nuclear magnetic resonance (NMR) analyses. Analytical methods for food products were reviewed by Chang et al. Of the 26-page review only one page is devoted to electrophoresis techniques, which shows that before the development of CE, electrophoretic procedures did not account for a major part of food analytical methods. Reviews of methods of food analysis have been published by Pare and Belanger and by Linden.

Electrophoretic techniques are all based on the differential migration of charged components when submitted to an electric field. The practical aspects of electrophoresis have been reviewed in great detail.
by Westermeier. The principles and applications of electrophoresis to the analysis of food and agricultural products were reviewed by Autran, who described four different modes of electrophoretic techniques:

1. mobile front electrophoresis
2. zone electrophoresis
3. IEF
4. ITP.

Only the last three have present-day applications.

2 GEL ELECTROPHORESIS

These methods separate components mainly according to size, the small molecules migrating faster than the larger ones. They are very powerful and are widely used in medical research for protein and nucleic acid analysis. However, since in most cases these techniques are not automated, they require skilled analysts and are usually time-consuming. Detection has been a major problem in gel analysis. Separated materials are trapped in a matrix and not easily quantified. Preferential staining of the proteins embedded in the gel with dyes or silver has been the main visualization method. Densitometric analysis of the stained proteins after removal of the excess dye has been the main quantitation procedure.

However, staining is linear only at low concentrations, it can vary between proteins and it is not exactly reproducible since many factors during separation, staining and destaining may affect the final gel (for a review, see Chen and Evangelista). Gels, however, are very convenient when radioactive compounds are monitored. Another technique of detection which has been particularly useful is immunoblotting. With this technique, molecules separated by an electrophoretic method are transferred from a gel to an immobilized membrane where reactions with ligands such as antibodies are performed. Reaction with its antibody can reveal the presence of a particular protein with great specificity or identify a protein in a one-dimensional gel.

2.1 Polyacrylamide Gel Electrophoresis

SDS PAGE is used for the analysis of peptides and proteins. The proteins bind to a negatively charged detergent (SDS) and are allowed to migrate in a polymeric gel. Since all SDS-protein complexes have similar mass-to-charge ratios, separation depends on the size of the protein. The pores of the gel can be controlled by modifying the acrylamide concentration and the level of cross-linkage of the polymer, which can be the same all over the gel or increase linearly or even exponentially. It is therefore possible to select a gel for a particular protein size range.

Gel electrophoresis is done either by disk electrophoresis, where a single analytical separation is performed in a cylindrical tube of gel or by slab electrophoresis, where separation occurs in a sheet of gel that can contain many individual wells. Electrophoresis can be continuous when the same gel and buffer are used or discontinuous when a stacking gel is used before the electrophoresis. Gel electrophoresis has been until recently the technique of choice for the analysis of peptides and proteins.

2.2 Isoelectric Focusing

In this technique, a pH gradient is formed in the gel by allowing the migration in the gel of amphoteric electrolytes, available commercially in many pH ranges. They are electrophoresed in the gel where they form a pH gradient. When submitted to an electric field, charged proteins move into the pH gradient until they reach their pI where they become neutral, stop and accumulate as a sharp peak that can be stained or used in 2-D slab gel.

2.3 Two-dimensional Gel Electrophoresis

Many proteins have identical or similar molecular weight (MW) or pI and are not separated by the methods examined so far. O’Farrell combined the IEF and SDS PAGE methods to separate proteins according to their pI and MW. The proteins are first separated on a disk gel by IEF. The gel is then deposited on a slab gel and the proteins are allowed to separate again according to their MW.

In the final 2-D slab gel, dozens of proteins may appear for a given MW and 1000 proteins can be revealed. This method is extremely powerful, but is very time-consuming and difficult to perform. We were able to detect minor changes in the protein composition of fish nervous tissues separated first by IEF between pH 4 and 8 followed by SDS PAGE between 10 and 200 kDa.

2.4 Agarose Electrophoresis

Agarose can also be used to make gels; such gels at a concentration of 1% have very large pores and are used for large proteins. Agarose gels are the main medium for the separation of DNA and RNA fragments. Pulsed field electrophoresis is used for nucleic acid separation. These methods have received only limited application in the area of food analysis; however, the recent introduction of genetically modified organisms in many food products has drastically increase the demand for DNA analysis of food components.
2.5 Nondenaturing Gel Electrophoresis

SDS and other chemicals such as urea and mercaptoethanol used in SDS PAGE produce the dissociation of the proteins into their individual subunits. The separation of native proteins can be done under conditions that preserve their conformation, subunit interactions and even biological activity. The original Ornstein–Davis buffer system is such a nondenaturing electrophoretic buffer.\(^{10,11}\)

2.6 Isoelectrofocusing

This electrophoretic system consists of a leading and a terminating electrolyte containing anions of greater and lower mobilities than that of the sample to be analyzed. During separation, a potential gradient is formed and zones containing individual substances are formed. The gel must allow the nonrestrictive migration of the protein, and polymer with only 5% acrylamide is often used. Proteins or ampholytes (spacers), with mobilities intermediate between those of two proteins being examined, can be added to improve separation.\(^7\)

2.7 Food Applications

Most of the methods examined so far are relatively complex and their use in food analysis has been mostly limited to research problems. Electrophoretic analysis of food, not including CE, has been reviewed by Autran\(^{15}\) and dealt mostly with protein analysis. The produce analyzed ranged from the egg content of pasta to milk proteins and wheat composition. A review on the use of electrophoretic techniques for wine study has been published by Carnellier et al.\(^{16}\) Proteins from specific animal species have been identified by electrophoresis; this is particularly important when one type of food is expensive and subject to fraud. Huang et al.\(^{17}\) identified red snapper by SDS PAGE, IEF and 2-D gel methods; the best results were obtained on 10–12.5% gel and an ampholyte mixture of 20% pH 3–10 and 80% pH 4–6.5. More recently, Hsieh et al.\(^{18}\) developed an IEF method for the identification of red snapper; they found that bands in the area (pH 3.5, 9.5) can be used as a marker for this fish.

Cereal genetics have been investigated by electrophoresis. Dougherty et al.\(^{19}\) examined 14 cultivars of hard red winter wheat and found a correlation between some gliadin and glutenin proteins and loaf volume. Furthermore, 2-D electrophoresis by the same group\(^{20}\) showed that image analysis of the 2-D gels provided a reproducible method for quantitating wheat proteins. A similar study was performed by Picard et al.,\(^{21}\) who analyzed durum wheat leaf proteins by 2-D electrophoresis and statistically analyzed the resulting gels to allow line identification. Corn zeins were examined by Drzewiecki\(^{22}\) by discontinuous PAGE. Changes in strawberry proteins labeled with \(^{35}\)Smethionine were examined using SDS PAGE.\(^{23}\) Various other types of food proteins have been also examined by electrophoresis. Santoro analyzed wine must proteins by IEF and SDS PAGE.\(^{24}\) Two consecutive series of stacking and running gels were used by Kubis and Gros to examine rabbit skeletal muscle.\(^{25}\) SDS PAGE (5%) and Western immunoblotting were used by Huff-Lonergan et al.\(^{26}\) to follow the post mortem degradation of titin and nebulin, two proteins associated with meat tenderness, in beef muscle. 2-D gel electrophoresis and antiserum reactions were used to isolate ADP-glucose pyrophosphorylase from tomato.\(^{27}\) Similarly, the isozymes of several citrus enzymes were followed by King et al.\(^{28}\) using PAGE analysis. Chalcone isomerase was examined by Fouche and Dubery\(^{29}\) by SDS PAGE, native PAGE analysis and IEF. King et al.\(^{30}\) separated citrus isozymes by PAGE using buffers best suited for each enzyme. The adulteration of goat cheese with cow milk was detected by Adddeo et al.\(^{31}\) using IEF of \(\beta\)-lactoglobulins. Antibiotic residues were detected in milk at the parts per billion level with a 2% agarose gel with a tris(hydroxymethyl)aminomethane (Tris) buffer (pH 8), followed by bioautographic detection with Bacillus stearothermophilus.\(^{32}\) Pulsed field gel electrophoresis was used by Izquierdo-Cana et al.\(^{33}\) to examine the electrophoretic karyotypes of 74 strains of Saccharomyces from fermenting wine musts.

3 CAPILLARY ELECTROPHORESIS

CE is a recent technique that has become widely adopted in the last few years with the availability of commercial instruments.\(^{34}\) Camilleri\(^{35}\) has published a history of CE showing the exceptional growth of this technique during the 1990s. CE has become a major analytical tool in the areas of pharmaceutical and food analysis. Such rapid development is due to several factors, but especially to speed and versatility. Most often separation can be performed in a few minutes with minimal sample preparation. The lack of precision noted in early instruments has been overcome and in many cases the precision and repeatability are similar to those obtained with high-performance liquid chromatography (HPLC) and superior to those provided by gel electrophoresis. Newer instruments have become particularly versatile with the introduction of modular apparatus, where a CE unit can be rapidly fitted with the appropriate detector chosen from a wide array of instruments available: detection by UV, diode-array, visible, fluorescence, conductivity and even mass spectrometric methods are
now possible.\textsuperscript{(36)} The rise in the use of CE in food analysis has been documented in several reviews. Early work was reviewed by Zeece\textsuperscript{(37)} and more recent work by several groups.\textsuperscript{(38–41)}

### 3.1 Capillary Electrophoresis Separation Techniques

The various CE procedures developed since the introduction of this technique have been extensively reviewed in many publications.\textsuperscript{(42–48)} Most of these techniques represent CE adaptation of procedures used in gel electrophoresis and described previously.

#### 3.1.1 Capillary Zone Electrophoresis

CZE can be viewed as the basic CE method from which all others are derived.\textsuperscript{(41–50)} CZE involves the use of a capillary tube usually made of fused silica with a diameter of 50–150 µm. The tube is filled with a buffer and subjected to an electric field, and under these conditions the positively charged species migrate toward the cathode at a rate determined by their mass-to-charge ratios. However, an EOF or net movement of the buffer toward the cathode is generated within the tube by the ionized capillary wall silanol groups. As a result, all the molecules present in the buffer proceed toward the cathode; the neutral molecules migrate as a single group transported by the EOF, and each negative species moves toward the cathode at a rate determined by the difference between the EOF and its anodic attraction.

#### 3.1.2 Capillary Wall Modifications

In CZE, the EOF controls the movement of all the transported molecules, so many efforts have been made to manipulate the process.\textsuperscript{(51,52)} The EOF can be slowed, stopped or even reversed. These EOF modifiers act by interacting with the capillary wall silanol groups. These compounds can be solvent additives that do not require modification of the capillary itself; other compounds are adsorbed on the wall while others are chemically bonded to the silanol groups. These modifications have allowed the development of separation using reversed polarity and are very useful for the separation of chemicals such as proteins that have a tendency to bind to capillary walls.

#### 3.1.3 Micellar Electrokinetic Chromatography

Many chemicals are either neutral or hydrophobic and cannot be readily separated by CZE. In MEKC,\textsuperscript{(53,54)} an anionic surfactant is added to the buffer to form negatively charged micelles. An analyte, depending on its hydrophobicity, will be partitioned between the water and the micelles. The mobility of the analyte will be determined by its own velocity in water, that of the micelles, the EOF and the partition coefficient between water and micelles.

#### 3.1.4 Chiral Electrophoresis

Chiral separation works on a principle similar to that of MEKC. Molecules such as a cyclodextrin (CD) can form complexes with other molecules depending on their spatial configuration. The migration velocity is dependent on the stability of the complexes and the migration rates of the various species. Separation of enantiomers is achieved if one configuration has more affinity for the CD than the other. Chiral CE has been extensively used in the analysis of pharmaceutical drugs (reviews are available\textsuperscript{(55,56)}).

#### 3.1.5 Isotachophoresis

In ITP, the sample is sandwiched between electrolytes of high and low mobility and the analytes migrate in order of decreasing mobility until a steady state is reached.\textsuperscript{(57)} This method has been useful for concentrating dilute samples.\textsuperscript{(58)} The actual instrumentation can be somewhat complex and can involve switching valves, since various buffers have to be injected.

#### 3.1.6 Isoelectric Focusing Electrophoresis

As seen previously, IEF is one of the main techniques used in protein gel electrophoresis, it is an essential part of 2-D gel electrophoresis and it has been adapted to CE. Amphoteric electrolytes are allowed to migrate in a capillary where they form a pH gradient. In such a gradient, proteins move until they reach their pI and accumulate as a sharp peak that can be subsequently eluted. Methods where the pH gradient and the separation are run consecutively or simultaneously have been developed.\textsuperscript{(59,60)} Even 2-D analyses have now been developed for CE.

#### 3.1.7 Polymer Sieving Electrophoresis

As for IEF, the techniques developed for disk and slab gels have been adapted to CE. Polyacrylamide and agarose gels have been used to separate proteins, carbohydrates and nucleotides. These filled capillaries can provide interesting results but they are relatively expensive and deteriorate rapidly. The capillary can also be filled with linear polymers such as noncross-linked acrylamide, which perform similar separations and have the advantage of being replaceable.\textsuperscript{(61)}

#### 3.1.8 Electochromatography

In the last few years, a new technique has been implemented that combines CE and HPLC.\textsuperscript{(62,63)} The
EOF is used as an electroosmotic pump to move the solvent rather than pressure as in HPLC. Typically, a 25-μm capillary is packed with a very fine material used in reversed-phase HPLC separation. A state-of-the-art review of capillary electrophromatography has been published by Stevenson et al. summarizing the potentials and drawbacks of this technique, which is still being developed and has not received large numbers of applications.

### 3.2 Detection

In early CE, detection was a major problem (for a review, see Albin et al.). Since the tube itself is used as the detection cell, the light path is very small, and the sensitivity is limited. In the last few years, considerable progress has been made and now CE detection is usually equivalent to that of other techniques. Many types of detection have been adapted to CE and with the introduction of modular equipment, easily replaceable detectors are available for the same instrument and in some cases can be used in series during an analysis.

#### 3.2.1 Ultraviolet/Visible Absorption

UV detection was the original CE detection method. Detectors using single and multiple wavelengths were first introduced. Diode-array and high-speed scanning have allowed the entire UV spectrum to be examined simultaneously. Many modifications of the detection system have been implemented to increase sensitivity. Changes in the capillary geometry such as local enlargement (bubbles) or Z cells have been used to increase the path, and UV lasers have been shown to enhance the detection limit (DL) up to fourfold. Many molecules such as carbohydrates, organic acids and inorganic ions do not absorb readily at the usual UV wavelengths. Indirect UV detection has been extensively used in CE analyses. With this method, a molecule absorbing strongly in the UV region is added to the buffer. During separation the nonabsorbing compounds displace the chromophore and create a zone of lower UV absorbance. As a result, a negative peak is created, that can be recorded and quantified.

#### 3.2.2 Fluorescence

Fluorescence detectors are now available for CE, and instruments with laser-induced fluorescence (LIF) have been shown to be particularly sensitive. Some compounds can fluoresce naturally but, in most cases, modifications of the molecules are necessary. Following derivatization of analytes such as amino acids (AAs) and peptides, detection at the attomole level has been reported. As with UV methods, indirect fluorescence detection is also possible.

#### 3.2.3 Electrochemical Detection

Electrochemical detection in CE was found to be technically complex, since the detector had to be separated from the capillary to avoid electric field interference. The detection had to be off- or end-column and until recently commercial instruments were not available. Conductivity detection in CE has been shown to be most useful for the analysis of organic and inorganic ions. Amperometric and particularly pulsed amperometric detection (PAD) are still not available at the commercial level although they would be extremely useful for sugar and carbohydrate analysis in food monitoring, but many laboratory-made instruments have been produced and provided excellent results.

#### 3.2.4 Derivatization

Derivatization of compounds with poor or no chromophores can greatly improve the detection of CE-separated chemicals. In CE most derivatizations are performed before the electrophoresis; however, some post- and even on-electrophoresis analyses have been performed. Added groups usually generate fluorescent or UV-absorbing molecules. Amines, aldehydes, ketones and carboxyl groups are most often targeted, and therefore derivatization has been mainly used to improve the detection of AAs, proteinaceous compounds and carbohydrates.

#### 3.2.5 Capillary Electrophoresis and Mass Spectrometry

In recent years, it has become possible to couple CE with electrospray MS using various interface techniques. These techniques are most useful for the identification and characterization of biological molecules. Protein and drug chemistry have so far been the main beneficiaries of these technical developments.

#### 3.2.6 Immunoassays and Affinity Electrophoresis

Finally, methods involving specific binding are also used in CE analysis. Immunoreaction with LIF is one of the most often used techniques where the antibody–fluorescently labeled antigen complex is revealed. Other types of receptor-ligand complexes such as enzyme–substrate complexes have also been used. This is done by producing either a mobile complex with specific migration properties or by immobilizing one of the components of the complex.
3.3 Application to Food Analysis

CE has proved to be effective in analyzing most of the molecules found in biological material. Any method that allows the analysis of the components of plant and animal tissues could also be used for food analysis, although the border between studies related to food and plant and animal physiology is somewhat blurred. Therefore, applications in other areas such as pharmaceutical and biomedical, plant and animal physiology are also relevant and may provide useful information for the examination of food components. Perrett(82) has reviewed the use of CE in biomedical and pharmaceutical research.

3.3.1 Carbohydrates

Several reviews on the analysis of saccharides by CE have been published.(83–86) New methods for the analysis of oligosaccharides have been examined by Grimshaw(87) and a detailed protocol for the CE analysis of oligosaccharides has even been reported by Linhardt(88) in Methods in Enzymology. However, relatively little work has been done in the area of food carbohydrate analysis, although simple sugars and oligo- and polysaccharides are very common and are extensively analyzed in food monitoring.

Saccharides absorb only in the far-UV region (at about 190 nm) and can be detected by direct UV detection. However, the sensitivity is not very good and many other compounds also absorb in this area of the spectrum, but since UV detectors are readily available, the far-UV region has been used to detect many chemicals. Direct UV analysis of sugars was performed using copper chelation.(89) More recently, direct UV detection at 192 nm was used by Zhong et al.(90,91) to separate pectins, an important food product, with a 50 mM phosphate buffer (pH 7). A similar separation was obtained with citrus pectins using a 30 mM borate buffer (pH 9.3) containing 5% acetonitrile with direct UV detection at 192 nm.(92)

The separation of borate complexes was one of the first types of CE analysis developed for saccharides. In the past, this method was used to examine pea oligosaccharides at 195 nm.(93) Indirect detection and borate complexation (200 mM) have been combined to analyze sucrose at the limit of 2 nM with p-nitrophenol as a chromophore at 400 nm.(94) A different approach was taken by Brewster and Fishman,(95) who measured a colored reaction product generated by the formation of complexes between starch and iodine with separation and detection in the visible region.

Indirect UV detection has been used extensively to analyze carbohydrates. The methods usually require a high pH to insure ionization of the sugars, but the sensitivity decreases at very high pH because of competition with hydroxide ions. The conditions for the indirect UV analysis of sugars were examined by Xu et al.(96) using sorbate, riboflavin and 3,4-dimethoxyxynamnic acid as chromophores. DLs 25 times better than those published with similar techniques were obtained with a riboflavin–NaOH buffer (pH 12.3). Specifically in food analysis, fruit juice sugars from apple, orange and grape were measured by Klockow et al.(97) and Klockow-Beck(98) by indirect UV detection, with a 6 mM sorbate buffer (pH 12.2). The same group(99) compared results obtained by their CE method and by HPLC/PAD. CE DLs were 0.2–0.3 mM whereas the PAD limits were as low as 0.5–1 μM. However, both methods gave accurate and reproducible results. Indirect UV detection was used to examine sugars (glucose, fructose and sucrose) in citrus juices; with sorbate at pH 11.5, sugars can be analyzed in 12 min.(100) The results for citrus juices were similar to those obtained by HPLC/PAD,(101) although the detection level of HPLC was much lower. However, the main advantage of CE over HPLC is that the method does not require any preparation apart from dilution and filtration. Similarly, sugars from soft drinks and uronic acids were separated by Zemann et al.(102) in 4 min with 6 mM sorbate buffer (pH 12.1) using reversed polarity with hexadimethrine bromide. The use of tryptophan (Trp) and N-benzylicchinonidium as a chromatophore has been shown to improve the sensitivity greatly over the use of sorbate.(103)

Saccharide detection can be greatly improved by attaching a probe to the compound to be analyzed. In addition to enhancing detection, the added tag can change the saccharide charge and modify the mobility, but derivatization increases the analytical time. Acidic monosaccharides were separated as sulfanilic acid or 7-aminothalylene-1,3,5-disulfonic acid derivatives.(104) This method was applied by the same group to the analysis of sialogangliosides.(105) Mono- and oligosaccharides were derivatized with 8-aminophenethalsulfonyl acid and separated by reversed polarity at pH 2.5.(106) The oligosaccharide composition of various beers was examined by Guttmann et al.(107) after labeling with the fluorophore 8-aminoopyrene-1,3,6-trisulfonate. Birch pulp xylan was analyzed by direct UV absorption at 232 nm after reduction of the acidic oligosaccharides with borate–NaOH buffer.(108) The authors further analyzed the acidic oligosaccharides with the same buffer and the neutral oligosaccharides after derivatization with 2-aminoquinoline using a similar buffer with detection at 245 nm. The MW of the analytes was determined by MS.(109) Cellulose degradation products were separated by Motellier et al.(110) using indirect UV detection, with 4 mM nicotinic acid as a chromatophore and 15 mM creatine on an uncoated capillary.

For many years, PAD has been the detection technique of choice for carbohydrate analysis by HPLC, where it
has been extensively used in food analysis to monitor sugar adulteration.\(^{101}\) However, no such detector is yet available commercially for CE. All the studies reported with PAD were performed with laboratory-made equipment, and detectors using copper electrodes were found to be well suited for CE analysis of sugars. Colon et al.\(^{111}\) used a copper microelectrode to examine glucose and fructose in carbonated soft drinks. A similar method was used by Ye and Baldwin\(^{112}\) who determined the saccharide composition of apple juice with a DL at or below the femtomole level. Weber and Lunde\(^{113}\) used CE/PAD to examine carbohydrates in a large number of biological materials such as bovine fetuin and coagulation factors; an 8 mM sodium borate buffer (pH 10.4) provided the best separation. Separation of polysaccharides according to molecular size was achieved by reversing the EOF with cetyltrimethylammonium bromide (CTAB).\(^{114}\) A copper(I) oxide electrode with 0.1 M NaOH solution was used by Huang and Koh\(^{115}\) to separate sugars at the micromole level. Sugars, sugar alcohols and sugar acids in fruit juices and soft drinks were examined by Goto et al.\(^{116}\) using amperometric detection with a copper electrode. The addition of cationic surfactant to the alkaline buffer doubled the sensitivity and a DL of 2.5 fmol was reported.

An interesting on-column enzymatic analysis of glucose was performed by Jin et al.\(^{117}\) Two enzymatic reactions were combined to generate fluorescent compounds and measure glucose at the nanomolar level in volumes as small as 200 nL.

### 3.3.2 Amino Acids and Proteins

Many techniques have been developed for AA analysis by CE and detailed reviews have been published,\(^{118,119}\) but so far the use of CE to examine AAs in food has been limited. As for carbohydrates, UV detection is not an ideal choice for AA analysis since they absorb only in the very far-UV region. Tolstra and Aristoy\(^{120}\) examined the essential AA composition of dry cured ham with citrate buffer (pH 2.5) and monitoring at 200 nm. A similar analysis was done on Cheddar cheese.\(^{121}\) Recently, Klampfl et al.\(^{122}\) analyzed free underivatized AAs by direct UV absorption at 185 nm with a 10 mM NaH\(_2\)PO\(_4\) buffer containing 30 mM octanesulfonic acid (pH 2.36). They used the method to analyze the AA composition of fresh and canned orange juice and several beers. Three aromatic AAs, namely, phenylalanine (Phe), tyrosine (Tyr) and Trp, absorb significantly in the UV region and were examined in citrus juice with a method developed for the general analysis of citrus juice by UV detection. Their presence in significant quantity was found to be associated with freshness.\(^{123,124}\) AA derivatives have also been examined. Tomlinson et al.\(^{125}\) examined the reaction products of 5-hydroxymethylfurural and glycine as a model of the Maillard reaction. The same group\(^{126}\) examined the colored products from the Maillard reaction with a phosphate buffer (pH 6.5), and showed a better separation of the products than with an HPLC method. A similar study was performed by Ames et al.\(^{127}\) 5-Hydroxymethyl-2-furaldehyde and 2-furaldehyde were estimated in fruit juices by MEKC with direct sample injection.\(^{128}\)

Derivatization represents an effective method for AA detection. Many types of reagents have been tried, with pre- and postcapillary derivatization and even within the capillary. Most molecules were UV absorbing or fluorophores. Dansylated AAs were separated by Skocir et al.\(^{129}\) from corn and seaweed, using MEKC with a 20 mM borax buffer (pH 9.2) containing 102 mM SDS. A very sensitive analysis of fluorescamine-labeled AAs and peptides in single nerve cells was described by Shippy et al.\(^{130}\) Electrochemical detection should improve the CE analysis of AAs.

Ye and Baldwin\(^{131}\) used CE with electrooxidation at a Cu electrode to examine AA mixtures at the 1–10-fmol level. The method was applied to the quantitation of aspartame in various soft drinks. A similar study was performed by Sabah and Scriba\(^{132}\) to examine the degradation of aspartame with a phosphate buffer at pH 2.7 and a borate buffer at pH 9.35. Amperometric detection was used by Guo et al.\(^{133}\) to examine AAs without derivatization with a strong alkaline buffer (pH 12). They used the method to analyze cytochrome c hydrolyzates.

Proteins have been extensively analyzed by CE, and a large number of reviews have been published since the mid-1990s.\(^{8,134–138}\) A review on the use of CE for the analysis of proteins and nucleic acids was published by Karger et al.\(^{134}\) and the principles of peptide analysis by CZE were reviewed by Wheat.\(^{135}\) Dolnik reviewed the use of CZE to analyze proteins.\(^{136}\) A complete review of protein analysis by CE has been published by Chen and Evangelista,\(^{8}\) Regnier and Lin\(^{137}\) and Schwartz et al.,\(^{138}\) who reviewed the CE separation of proteins and peptides. Detection is mostly done by direct UV absorption, but only three AAs (Phe, Tyr and Trp) absorb significantly in the UV region, and quantitation of different proteins may be difficult, since they may contain different proportions of these three AAs.

Many studies have been reported on the use of CE for food protein analysis. Recio et al.\(^{139}\) reviewed the use of CE for milk products analysis, including protein polymorphism, heat treatment, proteolysis and adulteration. The caseinomacropeptide from enzyme-treated acid casein and rennet whey were analyzed at pH 2.5 in 11 min, by a method that allows the determination of the kinetics of rennet coagulation.\(^{140}\)
Rennet whey solids in milk and buttermilk powder were further estimated for caseinomacropeptide by CZE using 6 M urea with a 0.15 mM citrate buffer\(^{[141]}\) and casein phosphopeptides were examined by Adamson and Reynolds.\(^{[142]}\) Paterson et al.\(^{[143]}\) separated lactoglobulin by CZE, the best separation being achieved with 50 mM 2-(N-morpholino)ethanesulfonic acid (MES), buffer (pH 8) containing 0.1% Tween and the same group\(^{[144]}\) compared CZE (150 mM borate buffer (pH 8.5) containing 0.05% Tween) with other methods of analyzing milk proteins. Cattaneo et al.\(^{[145,146]}\) also used CZE to analyze ewe milk. Milk proteins were extensively analyzed by Recio et al.\(^{[147]}\) They proteins were also analyzed\(^{[147]}\) using an uncoated capillary with a 100 mM borate buffer (pH 8.2) and 30 mM sodium sulfate. In order to detect adulteration of fresh milk with powdered milk, Recio and Olieman\(^{[148]}\) estimated heat-denatured proteins in casein on a hydrophilic column with a citrate buffer containing 6 M urea and detection at 214 nm. The same group\(^{[149]}\) compared CE, HPLC and gel isoelectrofocusing for the study of milk heat treatment CE separation was performed on an uncoated capillary with 100 mM borate buffer (pH 8.2) with 30 mM sodium sulfate. The authors concluded that CZE provided a better separation than HPLC. The same group\(^{[150]}\) studied the proteolysis of casein on a hydrophilic coated capillary with a citric acid–citrate buffer (pH 3) containing 6 M urea and 0.5 g L\(^{-1}\) methylhydroxyethylcellulose. Cow, goat and ewe milk mixtures were analyzed on a coated column with a citrate buffer (pH 3) at 40 °C. It was concluded that as little as 8% cow milk could be detected in goat or ewe milk. McSweeney and Fox\(^{[151]}\) used CE to follow cheese ripening.

Cereal protein composition is another area that has been extensively examined by CE. Werner\(^{[152]}\) used CE to analyze gliadins and glutenins in wheat and determine varietal origins. He used a coated column with an aluminum buffer (pH 2.3) or a capillary filled with a polymer and a buffer containing glycerol and methanol. Wheat gliadins were analyzed by Bietz\(^{[153]}\) with a phosphate buffer (pH 2.5) containing a linear hydrophilic polymer. Wheat glutenins\(^{[154]}\) were analyzed by CE with a commercial buffer containing 5% methanol and the separation was similar to that obtained by SDS PAGE. The authors also compared the reproducibility of their CE method for wheat identification.\(^{[155]}\) Lookhart and Bean\(^{[156]}\) analyzed oat and rice proteins by CZE with phosphate buffer (pH 2.5) containing 0.05% hydroxypropylmethylcellulose and concluded that CE performed as well as or better than PAGE or HPLC. The same authors\(^{[157]}\) analyzed wheat, oat and rice proteins on an uncoated column with a similar buffer containing 20% acetonitrile. The best separation of rice prolams was obtained when 26 mM laurylsulfobetain was added to the buffer. Gliadins were analyzed by Capelli et al.\(^{[158]}\) to discriminate wheat cultivars, using a buffer containing 40 mM aspartic acid with 7 M urea and 0.5% hydroxyethylcellulose. Gliadins were also examined by AbdelAal et al.\(^{[159]}\) Varietal differentiation of *Vicia* seeds was examined from their prolamine component by CE with a 200 mM borate buffer (pH 8.3) containing 8 mM SDS.\(^{[160]}\) Basha\(^{[161]}\) examined peanut proteins using a 0.3% borate buffer (pH 8.3) with an uncoated column and monitoring at 214 nm.

A general procedure for the analysis of food proteins (egg white, egg yolk and milk proteins) was developed by Chen and Tusak\(^{[162]}\) using untreated silica with a borate buffer (pH 10). The method was applied to egg white and yolk and also milk caseins and whey proteins. Separation of fermentation broth was achieved by Strege and Lague\(^{[163]}\) using a polyacrylamide-coated capillary. Wine proteins were analyzed by Luzguera et al.\(^{[164]}\) on an uncoated capillary with a 100 mM Tris–HCl buffer (pH 8) at 12 kV and detection at 214 nm. The method proved to be more sensitive than PAGE methods. Deng et al.\(^{[165]}\) separated tobacco seed proteins in 12 min with a 100 mM phosphate buffer containing 20% acetonitrile and 0.05% hydroxypropylmethylcellulose. Kajiwara and Hemmings analyzed ginseng polypeptides by CE.\(^{[166]}\)

Meat authenticity is another problem that has been investigated by CE, particularly for fish tissue. CZE at pH 7.4 was used by LeBlanc et al.\(^{[167]}\) to examine fish sarcoplasmic proteins. Several species of fish could be differentiated in less than 10 min with a 50 mM phosphate buffer, and it was concluded that this CE method was superior to conventional electrophoretic and HPLC procedures for the screening and monitoring of fish products. A similar study was performed by Gallardo et al.\(^{[168]}\) using CZE with 30 mM phosphate buffer (pH 2.44) and detection at 214 nm. Eight flatfish were examined and each species showed specific protein profiles that could be used for identification.

### 3.3.3 Lipids

Lipids are hydrophobic, often neutral and therefore difficult to analyze with conventional CE. To overcome technical problems, two approaches have been pursued: MEKC and CE in nonaqueous solvents. Nonaqueous CE has recently been reviewed by Miller and Khaledi.\(^{[169]}\) Previously, Blomberg and Andersson\(^{[170]}\) examined the use of CE in lipid analysis and described the separation of a mixture of isoprenyl pyrophosphate with indirect LIF detection. Nonionic aromatic compounds were examined by Shi and Fritz\(^{[171]}\) with a borate buffer containing 50 mM tetraheptylammonium bromide and 42% acetonitrile. MEKC was used by Ingvardsen et al.\(^{[172]}\) to separate phospholipids with a buffer containing cholate and propanol. Free fatty acids have been separated by CZE with
indirect UV detection using 5 mM diethyl butyrate as a chromophore (240 nm) in water–ethylene glycol ethyl ether containing 0.5 M trimethylammonium propanesulfonate at 45 °C. The method was applied to butter fatty acid separation after bromination of the double bonds.\(^\text{(173)}\) Indirect UV detection at 264 nm with 2.5 mM antraquinone-2-carboxylic acid and 40 mM Tris in \(N\)-methylformamid–dioxane was used by Drange and Lundanes\(^\text{(174)}\) to separate hydrogenated fish oil fatty acids. Skin fatty acids (steareate, oleate, palmitate and myristate) were separated by Neubert et al.\(^\text{(175)}\) with indirect UV detection, using 5 mM dinitrobenzoic acid, 10 mM phosphate buffer (pH 8) and 50% 1-propanol at 45 °C. The same group\(^\text{(176)}\) separated phospholipids in a nonaqueous buffer of acetonitrile–2-propanol–hexane (57:38:5) with 20 mM ammonium acetate, with characterization by MS. Kleinhenz and Harper\(^\text{(177)}\) examined short-chain cheese fatty acids. Hydroperoxides of unsaturated fatty acids were separated by MEKC with a buffer containing 70% 60 mM phosphate buffer (pH 6.3), 30% ethanol and 1.1 g L\(^{-1}\) 23-lauryl ether (Brij\(^\text{tm}\) 35) and detected in the UV region.\(^\text{(178)}\) MEKC with cholate was also used to analyze steroids by CE.\(^\text{(179)}\) Recently, Heinig et al.\(^\text{(180)}\) compared the analysis of saturated and unsaturated fatty acids from margarine and thistle oil by CE and HPLC. The CE method used indirect UV detection with 10 mM \(p\)-hydroxybenzoate, 5 mM Tris, 40 mM Brij\(^\text{tm}\) 35 and 50% acetonitrile. The authors concluded that the CE method was faster and easier to use but the HPLC procedure was more reproducible and sensitive.

### 3.3.4 Inorganic and Organic Ions

Numerous CE methods have been developed to analyze anions, cations and organic acids. The analytical procedures for these molecules are often grouped together since these ions can be separated by similar methods. In the last few years, a large number of reviews on the CE separation of ions have been published. Haddad published a review on the CE separation of inorganic ions\(^\text{(181)}\) in comparison with ion chromatographic techniques and concluded that the two methods should complement each other. A similar review was also presented by Buchberger.\(^\text{(182)}\) Macka and Haddad\(^\text{(183)}\) reviewed extensively the methods used for the CE analysis of metal ions. The formation of chelates and complexes was examined by Erim\(^\text{(184)}\) and Buchberger.\(^\text{(185)}\) The detailed procedures for the CE analysis of ions were explained by Jones.\(^\text{(186)}\) The separation of inorganic anions and cations has also been reviewed by Mazzeo,\(^\text{(187)}\) who examined the various techniques of inorganic ion analysis. Fritz\(^\text{(188)}\) reviewed the CE analysis of inorganic anions and metal cation analysis.

Most ions absorb only in the very far-UV region and, in most cases, indirect detection has been used for ion analysis. Chromate was one of the first chromophores used. Mazzeo\(^\text{(187)}\) optimized anion analysis using reversed polarity with 5 mM sodium chromate–3.5 mM tetradecyltrimethyl ammonium hydroxide (TTOH)–10 mM 2-(N-cyclohexylamino)ethanesulfonic acid (CHES) (pH 9.0) at 254 nm. Cousins et al.\(^\text{(189)}\) compared the effectiveness of several carrier electrolytes ranging from chromate to benzoate for the separation of small anions. Inorganic anions were also separated in nonaqueous media containing methanol and dimethylformamide.\(^\text{(190)}\) While anions are better separated with reversed polarity, cations can be run using direct polarity, with a complexing agent to improve separation; chemicals such as ethylenediaminetetraacetic acid (EDTA) interact with the cations and modify their mobility. Conditions for the indirect UV analysis of metal ions were examined by Chen and Cassidy.\(^\text{(191)}\) They examined the separation of 26 metal ions under various parameters such as the UV-absorbing probe, the pH, the concentration of the complexing agents and the nature of the capillary column. Alkali and alkaline earth metals in mineral water at the 0.1 mM level were studied by Simunicava et al. using tartrate, 18-crown-6 and benzimidazole as a visualization co-ion.\(^\text{(192)}\)

A similar separation of metal cations was obtained by Morin et al.\(^\text{(193)}\) using imidazole and benzylamine buffers.

They also explored in detail complexing agents that allow the separation of metal cations with similar mobility; of the chemicals they tried, they were most satisfied with phenylethylamine, benzylamine, \(p\)-toluidine and 4-methylbenzylamine. The same group examined minor cations in matrix samples.\(^\text{(194)}\) Indirect UV detection at 214 nm was used by Padaraska et al.\(^\text{(195)}\) to analyze simultaneously anions and cations. Each species is injected from a different end of the capillary and they migrate in opposite directions towards the detector; under these conditions three anions and five cations were separated in 4 min. Finally, conductivity and suppressed conductivity detection have been used. Avidalovic et al.\(^\text{(196)}\) separated many inorganic anions at the parts per million level. The same group\(^\text{(197)}\) still using suppressed conductivity detection, separated anions from fluorides to bromide with a 2 mM sodium tetraborate electrolyte with 5 mM sulfuric acid as regenerant. Using conductivity detection, Jones et al.\(^\text{(198)}\) separated 37 anions ranging from bromide to gluconate in about 12 min with a buffer containing 50 mM CHES, 20 mM lithium hydroxide and 0.03% Triton\(^\text{X-100}\) (pH 9.2).

Many reports on the use of CE to analyze inorganic ions in food products have been published. Indirect photometric detection with an imidazole–sulfuric acid buffer was also used by Yang et al.\(^\text{(199)}\) to measure K, Na, Ca and Mg in apple and orange juice, and A method has been developed to quantify K, Na, Ca, Mg and Mn in solid food: following digestion with \(\text{H}_2\text{O}_2\),...
the minerals were separated with 500 mM imidazole, 130.6 mM 2-hydroxyisobutyric acid and 50 mM 18-crown-6–20% methanol (pH 4.5). The method was applied to the determination of the composition of various teas.

Baechmann et al. (211) used indirect fluorimetric detection to examine alkaline earth metal ions in beverages, such as cola. Low MW ions in musts and wines were examined by Dedieu et al. (202) Several groups have analyzed nitrates and nitrites in food products. Stransky et al. (203) examined nitrates in milk by ITP. The concentrations of nitrate and nitrite in vegetables were measured with indirect UV detection. (204) Nitrites and nitrates were also examined in a large variety of foods ranging from cured meat to cheese and fruit juice with 0.5 mM OFM Anion-BT–1000 ppm chloride at 210 nm. (205) The same reagent diluted in 5 mM chromate was used by Trenerry to measure the sulfite level of many vegetables, processed foods and sea foods. (206) Calcium and magnesium in wheat flour were examined by Kajiwara et al. (207) using CZE. Mineral water anions and cations were analyzed simultaneously by Kobayashi et al. (208) with a borate buffer (pH 9) with 0.5 mM tetradecyltrimethylammonium bromide (TTAB).

Anionic impurities in glycerol were determined by capillary ITP (209) while inorganic anions and cations were examined at the single-cell level by Bazzanella et al. (210) Chloride, sulfate and nitrates were analyzed by Swallow and Low (211) at a level as low as 0.2 ppm using indirect UV detection. However, the authors were unable to use this technique to detect the addition of pulpwash (an orange juice by-product) to orange juice.

In CE, organic acids can be often separated with anions or at least can be followed by similar methods. Ion CE was described in detail by Jones (186) and Stover reviewed the CE analysis of organic acids and ions. (212) Like inorganic ions, organic acids absorb only in the very low-UV region and detection had to be done by indirect methods and more recently by conductivity detection. The formation of organic acids (lactic, acetic, phosphoric, citric, propionic, butyric) during lactic fermentation of various vegetables was examined by ITP and detected by a conductivity detector. (213) Buchberger et al. (214) studied fermenting acids in silage using indirect UV detection with sorbate or direct UV detection at 185 nm. Acetic, lactic and butyric acids were measured. ITP has been used by Kvasnicka et al. (215) to monitor metals, organic and inorganic acids and volatile fatty acids during sugar production. Lalljje et al. (216) analyzed organic acids in juice produced during sugar refining and in chicory root extract.

Hop bitter acids have been analyzed by various groups. Szucs et al. (217) were able to analyze directly iso-α-acids in beer by sample stacking of large injected volumes. They obtained similar separation by microemulsion electrokinetic chromatography. (218) Organic acids in beer were also examined by CZE. (219) Inorganic and organic anions, ranging from chloride to pyroglutamate, have been analyzed in beer and wort in less than 7 min using indirect UV detection at 350 nm and reversed polarity with a buffer containing 5 mM 2,6-pyridinedicarboxylic acid and 0.5 mM CTAB. (220) CE (phthalate buffer, pH 5.6) and HPLC were compared by Levi et al. (221) to study organic acids in wine, and they found that the two techniques gave similar results. In wine, molecules ranging from chloride to lactic acid were separated in 10 min. (222) Isocitric, citric, malic and tartaric acids were separated from orange juice in 14 min with inverse polarity and a buffer containing phthalic acid, CTAB and 20% methanol at pH 7. (223) Lazzarelli et al. (224) used chromat and phthalate with a modified OFM Anion-BT buffer to examine organic acids (citric and malic) and inorganic acids in fruit juices and particularly orange juice. Citrus organic acids, namely citric, malic and isocitric acid, were examined with several methods. (225, 226) Isocitric acid is present in orange juice in very small amounts compared with the other two acids. Furthermore, some of these acids are bound and must be hydrolyzed before analysis. Hydrolysis was performed with a procedure similar to that used for the enzymatic analysis of isocitric acid. A 5 mL volume of 4 M sodium hydroxide solution was added to 10 mL of juice to raise the pH to about 13.5. After 10 min, 5 mL of 4 M HCl were added to the solution to decrease the pH to 5.5. With indirect UV detection and monitoring at 205 nm, organic acids were first examined with direct polarity. Using 5 mM phthalate (pH 3.5) at 20°C and 30 kV, under these conditions standards of these three acids were well separated but in the juice only citric and malic were separated. (225) Under different conditions (5 mM phthalate, pH 3.6, with 3 M CaCl₂ at 15°C and 30 kV), isocitric acid in juice could be seen, but the best separation with indirect UV detection was achieved with reversed polarity and a buffer containing 5 mM phthalate, 0.5 mM TTAB and 50 mM N-tris(hydroxymethyl)-2-aminoethanesulfonic acid (TES) (pH 8) at −15 kV and 20°C. With this method, citric and malic acids were easily measured but isocitric acid was difficult to resolve and a separate run was necessary. Conductivity detection gave more precise and more reliable data and the three acids could be measured in a single run. The following conditions were used: 130 mM histidine, 130 mM MES, 0.7 mM TTAB, 0.03% Triton™ X-100, 10 ppm EDTA and 15% acetonitrile, pH 6, 21°C and −18 kV. The results obtained by conductivity detection for the three organic acids were similar to those reported by three different laboratories using conventional enzymatic methods. (226)

3.3.5 Vitamins and Plant Chemicals

Since ascorbic acid is water soluble and absorbs very well in the UV region, it has been monitored by...
many groups. Extraction with metaphosphoric acid and stabilization with dithiothreitol were used by Thompson and Trenerry\(^{227}\) with MEKC and a sodium deoxycholate buffer to assess total L-ascorbic acid in fruits and vegetables. The dithiothreitol reduces the dehydroascorbic acid to ascorbic acid and allows the estimation of the total amount of vitamin C. The authors used a similar method to measure ascorbic acid in beers, wines and fruit beverages.\(^{228}\) Cahill and Wightman\(^{229}\) also measured ascorbate and catecholamine by CE. L- and D- ascorbic acid have been analyzed by Davey et al.\(^{230}\) in parsley and mushroom after extraction with metaphosphoric acid with 200 mM borate buffer (pH 9) at 260 nm. The method has a limit of detection of 84 fmol per injection. On comparing HPLC and CE methods, the authors found CE to be more suitable for the analysis of low vitamin concentrations in certain complex matrices, such as mushroom. A complex ITP/CZE method was used by Prochazkova et al.\(^{231}\) to measure trace amounts of ascorbic acid in human body fluids with a sensitivity of 0.09–0.15 mg L\(^{-1}\). Vitamin C is routinely measured by CZE as part of a general analysis of citrus juices (see below); from the multiwavelength electropherogram the 280 nm trace is extracted and ascorbic acid measured. The results are similar to those obtained by HPLC.\(^{224}\)

Huopalahi and Sunell\(^{232}\) monitored simultaneously vitamins B\(_1\), B\(_2\) and B\(_6\) by CZE. Up to nine water-soluble vitamins (vitamins C, B\(_1\), B\(_3\), B\(_6\) and B\(_12\), folinate, orotic acid, pantothenate and nicotinamide) were separated by Jegle\(^{233}\) with a phosphate buffer (pH 7). L- and D- folic acids were separated by Cellai et al.\(^{234}\) using CD as a chiral active component. Choline was examined in foods and infant formula with a 5 mM 1-methylimidazole buffer (pH 4.5).\(^{235}\) Niacin in yeast spread was extracted by autoclaving in calcium hydroxide and separated by CE with a 1:1 mixture of 0.02 M sodium tetraborate and 0.02 M disodium hydrogenorthophosphate (pH 9.2).\(^{236}\) The results were similar to those obtained by the traditional colorimetric procedure. The authors\(^{237}\) measured niacin in various foods with a buffer containing 0.02 M phosphate buffer (pH 7) with 15% acetonitrile. Hsieh and Kuo\(^{238}\) separated retinoids by MEKC. Fourteen water-soluble vitamins and vitamin cofactors were investigated by MEKC in foods such as orange juice with a buffer containing 100 mM phosphate, 500 mM taurine, 75 mM cholate and 2% propanol.\(^{239}\) Pedersen-Bjergaard et al.\(^{240}\) separated fat-soluble vitamins by hydrophobic interaction electrokinetic chromatography. Vitamins A, D and E were separated on an uncoated fused-silica capillary with a buffer of acetonitrile–water (80:20) and 80 mM tetra-decylammonium bromide.

The CE analysis of plant chemicals has seen a major increase in the last few years and is one of the main areas of CE use for food products. A review of the CE analysis of natural products has been published by Issaq.\(^{241}\) Many of these natural compounds absorb in the UV region and can be easily examined with most instruments. Sugarcane flavonoids have been examined by CZE with a borate buffer (pH 9.5) and 20% methanol.\(^{242}\) Pietta’s group reported several studies on the analysis of flavonoids. They used MEKC and diode-array ultraviolet detection (DAD/UV)\(^{243,244}\) to separate flavonoids. They further\(^{245}\) used MEKC with a 25 mM buffer (pH 8.25) with 50 mM SDS to analyze components from the root of Eleutherococcus senticosus and to detect adulteration in Arnica montana and chamissonis.\(^{246}\)

Morin et al.\(^{247}\) studied the complexion of borate and flavonoids. Shihabi et al. compared the HPLC and CE separation of isoflavones.\(^{248}\) The HPLC method required a complex isocratic elution whereas the CE separation was done on a simple capillary with a borate buffer at pH 8.6 and took less than 8 min. A comparison between CE and HPLC for the analysis of honey flavonoids has been reported by Delgado et al.\(^{249}\) and by Ferreres et al.,\(^{250}\) who used MEKC, with a borate buffer (pH 8) containing 50 mM SDS and 10% methanol, to differentiate various types of honey by their flavonoid content. The influence of temperature on the CE separation of flavonols was studied by Fernandez de Simon et al. using a boric acid buffer (pH 9.6).\(^{251}\)

Shepherd and McGhie\(^{252}\) used CE with a tetraborate buffer to measure chlorogenic acid, apigenin, isoorientin and querctin and the method was used to monitor the activity of polyphenol oxidase. Gil et al. developed an MEKC method to separate methylated flavones\(^{253}\) and analyzed the phenolic compounds in red wine\(^{254}\) with a borate buffer at pH 9.5 in a fused-silica column. From the results they were able to differentiate wines from different areas. Citrus seed limonoids (limonin and nomilin) were quantified by MEKC with a 12 mM tetraborate buffer containing 35 mM SDS.\(^{255}\)

The composition of Chinese herbal tea including the flavonoid constituents was examined by Sheu and Chen\(^{256}\) by HPLC and CE. Rhubarb aloe-emodin, emodin and rhein were measured by MEKC with a buffer containing 3-(cyclohexylamino)-1-propanesulfonic acid (CAPS), SDS and acetonitrile at pH 10.96.\(^{257}\) Ferulic and coumaric acids and esters and feruloyl glucosides from wheat bran were analyzed by Donaghy and McKay\(^{258}\) using CZE. Flavonoids and cinnamic and phenolic acids were separated from blackcurrant bud extracts with a buffer containing 50 mM phosphate and 100 mM boric acid (pH 7) at 50°C and 20 kV with detection at 232 nm.\(^{259}\) Liang et al.\(^{260}\) used an MEKC method to analyze the flavonoid content of four species of Epimedium with a buffer containing 30 mM borate and 12 mM SDS (pH 10.5) at 22 kV. The same group analyzed in detail the migration properties of flavonoids.\(^{261,262}\)
Isoflavones from Lodoideae and Leguminosae were studied by CE/MS with an ammonium acetate buffer (pH 9.5). Chrysanthemum coumarins were examined by CE with 0.2 M boric acid–0.05 M borax (11:9) (pH 8.5) while Chen and Sheu used MEKC to separate coumarins. Coumarin derivatives were followed by Bogan et al. Fourteen plant phenolic compounds were separated by Jen et al. with a borate buffer (pH 9) and detection at 210 nm; the DLs ranged from 20 to 100 µg L⁻¹. Tea polyphenols were separated by Larger et al. with a buffer containing 20 mM SDS, 50 mM phosphate and 50 mM tetaborate with 10% acetonitrile (pH 6) and detection at 278 nm. Hiermann and Radl separated aromatic acids from *Epilobium angustifolium* L. with a 20 mM phosphate buffer (pH 7.0) at 40°C; peaks were detected at 280 nm. We routinely examine citrus juices for hesperidin, neohesperidin, narirutin and naringin to assess the purity of the products (see below). Anthocyanins are another group of plant chemicals that have received attention from CE analysts. In 1996, Bridle et al. developed a method to detect anthocyanins at 580 nm, using a 150 mM sodium borate buffer (pH 8) at 25°C. The same system was used by this group to examine anthocyanins in strawberries and elderberries and the results were compared with those obtained by HPLC, which gave better separation for the latter fruit. The same chemicals were separated from blackcurrant with a strongly acidic phosphate buffer (pH 1.5) containing 30% acetonitrile. Watanabe et al. used CE to separate safflower pigments. The yellow watersoluble pigment could be analyzed with a 300 mM borate buffer (pH 9) and both yellow and red pigments could be separated by MEKC with 2% butyl acrylate–butyl methacrylate–methacrylic acid polymeric acid, and caffeine and its metabolites were analyzed by MEKC.

### 3.3.6 Additives, Toxins, Drugs, Pesticides

The monitoring of food products requires the constant examination of many drugs, food additives and degradation products to indicate whether a product is fit for consumption. The analysis of food additives by CE has been reviewed by Schuster, pollutants by Dabek–Zlotorzynska, pharmaceutical drugs by Shihibi and pesticides by El Rassi. Alkaloids can be responsible for various food poisonings and have been followed by CE. Ergovaline in seeds was measured by Ma et al. with a phosphate buffer (pH 3.5) containing 50% methanol. Liu and Sheu used CE to compare alkaloid compositions in samples of *Ephedrae herba* and *Phellodendri cortex*. Alkaloids from various plants were analyzed by Unger et al. using field amplified sample injection of a 70% methanol solution into a buffer of 200 mM ammonium acetate (pH 3.1)–methanol (1:1) and further studied the influence of the alkaloid structure on mobility. Vandeper et al. used MEKC buffers to examine alkaloids and vanillin benzoate in various drinks and confectionery. Ergot alkaloids have been separated with a phosphate buffer (pH 2.4) containing cetyltrimethylammonium bromide, urea and poly(vinyl alcohol). Strychnine and brucine from *Strychnos nux-vomica* were quantified with 10 mM phosphate buffer–methanol (9:1) at pH 2.4. Yang and Smetena separated nicotine and other alkaloids from tobacco with a 120 mM phosphate buffer (pH 2.7). The Chinese drugs tetrandrine and fangchinoline were examined by Yang et al.

A CE immunofluorescence method was used by Blais et al. to determine chloramphenicol in milk; bound and unbound forms of the chloramphenicol conjugate were titrated with LIF detection. Sorbic acid and benzoic acid in foods and beverages were separated by Pant and Treenary with a 0.02 M phosphate buffer (pH 9.2) and 0.05 M SDS by MEKC. We routinely monitor sorbate and benzoate in citrus juice with a direct CZE analysis using a borate buffer. Dinelli et al. compared CE, HPLC and immunoassay for the detection of the herbicide terbutylazine in tap water. CE gave the best sensitivity and the shortest retention time; however, CE and HPLC require prior extraction of the sample. The same group used MEKC to quantify sulfonylurea herbicides at the parts per billion level. Nine herbicides were separated in 16 min by Farran and Ruiz with an MEKC buffer. Wigfield et al. analyzed paraquat and diquat in potatoes on a silinazed column; the method was shown to be superior to an HPLC method. Herbicides were also separated by Schmitt et al. by CZE. Nemoto and Lehotay used a 50 mM ammonium acetate buffer (pH 4.75) to follow pesticides extracted from soybean by pressurized liquid extraction. Alcantara et al. analyzed the pesticides phloxine B and urarine in coffee by CZE with a borate buffer (pH 8.5) and UV and fluorescence detection. Results similar to those obtained by HPLC were reported.

Using 1-naphthol-3,6-disulfonic acid as a chromophore, Buscher et al. monitored the enzymatic hydrolysis of inositol phosphates (such as phytic acid from grain) during fermentation. Phytic acid was analyzed in plant material with a fluorinated ethylene–propylene copolymer capillary associated with two conductivity cells. Mycotoxins fumonisins were examined by Maragos after derivatization with fluorescein isocyanate. The two isomers of the neurotoxin 2-(N-oxayl)-L-2,3-diaminopropionic acid (ODAP) were measured in grass peas with a phosphate buffer (pH 7.8) with direct UV detection at 195 nm. Sciachitano and Hirshfield used CE to identify the *Clostridium botulinum* type E neurotoxin gene in smoked
fish and fungal metabolites were examined by Nielsen et al. with MEKC.

Toxic degradation products in food are monitored very closely and CE is now playing a role in these analyses. Mopper and Sciacchitano measured histamine in fish with a citrate buffer (pH 2.5), and showed that the method was superior to the official AOAC fluorimetric method, particularly at low concentrations. The authors also reported distinct electropherograms for various fish species. Buzy et al. used a buffer containing morpholine at pH 4 to estimate shellfish poisoning toxins. A 50 mM phosphate buffer (pH 2.44) was used by Gallardo et al. to quantify histamine in fish and fish products and to identify fish species. Zhao et al. separated domoic acid in fish products with a buffer of 22.5 mM borate (pH 9.2) and 20 mM β-CD and Bouaicha et al. used MEKC to monitor okadaic acid. Separation of nitrosamines was achieved with a CD-modified MEKC and a combined packed and open-tubular column.

5-(hydroxymethyl)-2-furaldehyde (HMF) in jam and soft drinks and furosine in dry milk were examined by Corradini et al. using MEKC; a mean concentration of 4.6–74.2 mg of HMF was detected in soft drinks. Furosine as an indicator of heat treatment in milk and cheese was measured by Tirelli and Pellegrino with a 100 mM phosphate buffer (pH 7).

Indirect UV detection was used by Trevaskis and Trener to determine oxalic acid, nitrate and molybdate in vegetables. Artificial sweeteners can easily be detected in the UV region and several analyses have been published. Liu and Li compared CE and HPLC for the analysis of Stevia sweeteners. As seen previously, Sabah and Scriba examined aspartame. MEKC with a sodium deoxycholate buffer was used by Thompson et al. to measure many artificial sweeteners in soft drinks. Using the same technique, the authors also examined synthetic colors in confectionery and cordials using an MEKC buffer. Food colorants were also

![Figure 1](image-url)  
**Figure 1** (a) Three-dimensional electropherogram of orange juice. The third dimension is produced by stacking electropherograms produced at many wavelengths; as a result the spectrum of each separated compound is produced. Syn = synephrine; Did = didymin; Hesp = hesperidin; Nar = narirutin; Phlo = phlorin; Phe = phenylalanine; Tyr = tyrosine; Asc = ascorbic acid, Fer = ferulic acid (internal standard). (b) 200, 230 and 280 nm traces extracted from the three-dimensional electropherogram.
examined by Razee et al.\textsuperscript{(320)} using CD and by Liu et al.\textsuperscript{(321)} Eleven phenolic antioxidants were separated by Abrantes et al.\textsuperscript{(322)} by MEKC with a buffer containing 15 mM SDS, 50 mM phosphate and 25 mM borate (pH 7).

3.3.7 Food Monitoring

Several studies have shown that a single CE analysis can be used to separate and quantify chemically unrelated components of the same matrix. For example, the quality of green tea was monitored by Horie and Kohata\textsuperscript{(323)} using a sodium borate buffer containing 50 nM SDS at pH 8.4. Detection was effected at 194 nm for all compounds except ascorbic acid, which was examined at 270 nm. From the data it was possible to estimate the quality of the teas. Various types of teas were also examined by Larger et al.,\textsuperscript{(269)} who analyzed xanthine, catechin and flavonol by MEKC with a buffer containing 20 mM SDS, 50 mM phosphate, 50 mM sodium tetraborate and 10% acetonitrile (pH 6). Each type of tea has a specific profile that allows its identification. Brandy and oak extracts were analyzed by CE and HPLC.\textsuperscript{(324)} The CE analysis was done with a 0.1 M borate buffer containing 5% ethanol (pH 9.2). It was concluded that CE and HPLC are complementary and the CE method could be used to assess the quality and authenticity of brandies.

In the past, the monitoring of citrus juices was done by a series of analyses using HPLC and spectrophotometric methods. A CE method to analyze simultaneously many citrus juice components in a single procedure has been reported.\textsuperscript{(123,124)} Following filtration, the samples are analyzed, in 20 min, with an uncoated capillary using a 35 mM sodium borate buffer (pH 9.3) containing 5% (v/v) acetonitrile at 21 kV and 23 °C. The main compounds monitored on a regular basis are a biogenic amine (synephrine), some flavonoids (didymin, narirutin, neohesperidin and naringin), the polyphenol phlorin, three AAs absorbing in the UV region (Trp, Phe and Tyr), ascorbic acid, an unidentified peak generated by heat and storage and two preservatives (sorbate and benzoate) that can be added to citrus products (Figure 1). Each compound can subsequently be quantified. The didymin, narirutin and phlorin peaks are used with an artificial neural network to assess the volume of added pulp wash, a by-product of juice preparation. This last procedure is equivalent to the quantitation of a blend of two similar juices. This CE method allows the rapid monitoring of citrus juices, giving information on the quality, freshness and possible adulteration of the product. Similar procedures could be used to monitor other fruit juices and quantify diverse juice blends.\textsuperscript{(325)}

4 CONCLUSION

Food analysis is largely dominated by HPLC methods and most electrophoretic techniques have seen only limited use in this area. However, studies published in the last few years have shown a large increase in the use of CE for the analysis of food components. Food examination by CE should continue to expand since many procedures developed for other biological materials could and probably will be applied to edible products. Several reasons can be found to explain the rise of this technique. Most CE separations can be performed in a few minutes with little sample preparation. As opposed to HPLC, CE requires small volumes of solvents and, contrary to other electrophoretic techniques, can be easily automated. It allows many compounds of different chemical nature to be separated in a single analysis, hence CE is most useful for analyzing rapidly large numbers of samples. Further developments should be mainly in the area of food quality monitoring.

The objectives for carrying out analysis of food products include food safety, food quality, meeting regulatory requirements and the control of food processes. Biological tools used in food analyses include enzymes, microbes and antibodies. These biological entities can play a role in accomplishing each of the principal purposes of food analysis. Based on these categories of analysis, general principles of enzyme, immunological and whole organism (microbial) analyses are given. Applications of the use of enzymes for substrate analysis, with examples of their application, are presented. A brief description is given of the use of enzymes as preparative tools in food analysis, and of biosensors that use enzymes as elements. Immunological analyses applicable to food systems are given, with an emphasis on applications related to food safety. Microbial assays used in food analysis are described, including vitamin analysis, detection of antibiotics and assessment of protein quality.

2 ENZYMOLOGY

2.1 Overview

Enzymatic analysis is the measurement of analytes with the aid of added enzymes or the measurement of endogenous enzyme activity to give an indication of the state of a biological system including those related to food. Enzyme catalysis can take place under relatively mild conditions, allowing for measurement of relatively unstable compounds not amenable to some other techniques. In addition, the specificity of enzyme reactions can allow for measurement of components of complex mixtures without the time and expense of complicated separation techniques.

There are several uses of enzyme analyses in food science and technology. In several instances, enzyme activity is a useful measure for adequate processing of a food product. Enzyme activity assays are also used by the food technologist to assess potency of enzyme preparations used as processing aids.

Food scientists also use commercially available enzyme preparations to measure constituents of foods that are enzyme substrates. A corollary of the use of commercially available enzymes is to measure enzyme activity as a function of enzyme inhibitor content in a food. For example, organophosphate insecticides are potent inhibitors of the enzyme acetylcholinesterase, hence the activity of this enzyme in the presence of a food extract is a measure of this category of insecticide concentration in the food. Also of interest is the measurement of enzyme activity associated with food quality. Another use of enzyme assays to determine food quality is estimation of protein nutritive value by monitoring the activity of added proteases on food protein samples. Enzymes can also be used to measure the appearance of degradation for the control of food processes.
2.2 Kinetics

Enzymes are proteins that are biological catalysts. A catalyst increases the velocity of a thermodynamically possible reaction. The enzyme does not modify the equilibrium constant of the reaction, and the catalyst is not consumed in the reaction. Because enzymes affect rates (velocities) of reactions, some knowledge of enzyme kinetics is needed to use enzymes effectively in analysis. To measure the rate of an enzyme-catalyzed reaction, typically the enzyme is mixed with the substrate under specified conditions (pH, temperature, ionic strength, etc.) and the reaction is followed by measuring the amount of product that appears, or by measuring the disappearance of substrate. Consider Equation (1) as a simple representation of an enzyme-catalyzed reaction:

\[
S + E \underset{\text{eqilibrium}}{\overset{\text{products}}{\rightarrow}} ES \rightarrow P + E
\]

where S is the substrate, E is the enzyme, ES is the enzyme–substrate complex and P is the product.

The formation of the enzyme–substrate complex is very rapid and is not normally seen in the laboratory. The brief time in which the enzyme–substrate complex is initially formed is on the millisecond scale and is called the presteady state period. The rate of change of the product concentration following the presteady state period gives us the initial velocity \(v_0\). After the presteady state period, a steady state period exists in which the concentration of the enzyme–substrate complex is constant. A time course needs to be established experimentally by using a series of points or a continuous assay to establish the appropriate timeframe for the measurement of the initial velocity.

The rate of an enzyme-catalyzed reaction depends on the concentration of the enzyme and also on the substrate concentration. With a fixed enzyme concentration, increasing substrate concentration will result in an increased velocity. As substrate concentration increases further, the increase in velocity slows until, with a very large concentration of substrate, no further increase in velocity is noted. The velocity of the reaction at this very large substrate concentration is the maximum velocity \(V_m\) of the reaction under the conditions of that particular assay. The substrate concentration at which one-half \(V_m\) is observed is defined as the Michaelis constant \(K_m\), an important characteristic of an enzyme.

For a particular substrate. The lower the \(K_m\), the greater the affinity of the enzyme for the substrate. Equation (2) is the Michaelis–Menten equation, the equation for a right hyperbola.

\[
v_0 = \frac{V_m[S]}{K_m + [S]} \tag{2}
\]

2.2.1 Order of Reaction

The velocity of an enzyme-catalyzed reaction increases as substrate concentration increases, as noted above. A first order reaction with respect to substrate concentration is obeyed when substrate concentration is small ([S] \(\ll K_m\)). This means that the velocity of the reaction is directly proportional to the substrate concentration in this region. When the substrate concentration is further increased, the velocity of the reaction no longer increases linearly, and the reaction is mixed order. If substrate concentration is increased further, the velocity asymptotically approaches the maximum velocity \(V_m\). Under these conditions, the velocity is independent of substrate concentration. Note that at large substrate concentrations ([S] \(\gg K_m\)), the velocity is directly proportional to enzyme concentration \(V_m = k_2[E_0]\). Thus, where [S] \(\gg K_m\), the rate of the reaction is zero order with respect to substrate concentration (is independent of substrate concentration) but first order with respect to enzyme concentration.

Thus, if one is interested in measuring the amount of enzyme in a reaction mixture, if possible substrate concentrations should be used so that the observed velocity approximates to \(V_m\). Conversely, if one is interested in measuring substrate concentration by measuring initial velocity, substrate concentrations less than \(K_m\) must be used, in order to have a rate directly proportional to substrate concentration.

2.3 Factors that Affect Enzyme Reaction Rate

The velocity of an enzyme-catalyzed reaction is affected by a number of factors, including enzyme and substrate concentrations, temperature, pH, ionic strength, and the presence of inhibitors and activators. The velocity of an enzyme-catalyzed reaction will depend on the enzyme concentration in the reaction mixture, and doubling the enzyme concentration should double the rate of the reaction. It is critical that the substrate concentration is saturating during the entire period the reaction mixture is sampled and the measured amount of product formed or substrate disappearing is linear over the period during which the reaction is sampled. The activity of the enzyme is obtained as the slope of the linear part of the line of a plot of product or substrate concentration versus time. If a large number of samples are to be assayed, a single aliquot is often taken at a single time. This will
give good results only if the time at which the sample is taken falls on the linear portion of a plot of substrate concentration or product concentration versus time of reaction. The plot becomes nonlinear if the substrate concentration falls below the concentration needed to saturate the enzyme, if the increase in concentration of product produces a significant amount of back reaction, or if the enzyme loses activity during the time of the assay. Normally, an experiment is designed in which enzyme concentration is estimated such that no greater than 5–10% of the substrate has been converted to product within the time used for measuring the rate. A better method of estimating rates is to measure initial rates of the reactions, in which the change in substrate or product concentration is determined at times as close as possible to time of initiation of the reaction.

Sometimes it is not possible to carry out enzyme assays at $[S] \gg K_m$. The substrate may be very expensive, relatively insoluble, or $K_m$ may be large (i.e. $K_m > 100$ mM). When substrate concentration is much less than $K_m$, the substrate term in the denominator of the Michaelis–Menten equation can be ignored and $v = (V_m[S])/K_m$, which is the equation for a first-order reaction with respect to substrate concentration. Under these conditions, a plot of product concentration versus time gives a nonlinear plot. A plot of log([S]/[S]) versus time gives a straight line relationship. The slope of the line of the log plot is directly related to the enzyme concentration. When the slope of a series of these log plots is further plotted as a function of enzyme concentration, a straight line relationship should result. If possible, the reaction should be followed continuously or aliquots removed at frequent time intervals.

2.3.1 Effect of Temperature

Temperature can affect observed enzyme activity in several ways. Most obvious is the fact that temperature can affect the stability of the enzyme and also the rate of the enzyme-catalyzed reaction. Other factors in enzyme-catalyzed reactions that may be considered include the effect of temperature on the solubility of gases that are either products or substrates of the observed reaction, and the effect of temperature on the pH of the system. A good example of the latter is the common buffering species Tris (tris(hydroxymethyl)aminomethane), for which the $pK_a$ changes 0.031 per 1°C of change.

Temperature affects both the stability and the activity of the enzyme. At relatively low temperatures, the enzyme is stable. However, at higher temperatures denaturation dominates and a markedly reduced enzyme activity is observed. The velocity is expected to increase as the temperature is increased. The velocity approximately doubles for every 10°C rise in temperature. The temperature optimum is not a unique characteristic of the enzyme. The optimum applies instead to the entire system because type of substrate, pH, salt concentration, substrate concentration and time of reaction can affect the observed optimum. For this reason, investigators should fully describe the system in which the effects of temperature on observed enzyme activity are reported.

2.3.2 Effect of pH

The observed rate of an enzyme-catalyzed reaction is greatly affected by the pH of the medium. Enzymes have pH optima and commonly have bell-shaped curves for activity versus pH. The observed effect of pH on enzyme activity is a manifestation of the effects of pH on enzyme stability and rate of substrate to product conversion, and may also be due to changes in ionization of the substrate.

To establish the pH optimum for an enzyme reaction, the reaction mixture is buffered at different pHs and the activity of the enzyme is determined. To determine pH–enzyme stability relationships, aliquots of enzyme are buffered at different pH values and held for a specified period of time (e.g. 1 h). The pH of the aliquots is then adjusted to the pH optimum, and each aliquot is assayed. These studies are helpful in establishing conditions for handling the enzyme, and may be useful in establishing methods for controlling enzyme activity in a food system. Note that pH stability and the pH optimum for the enzyme activity are not true constants. These may vary with a particular source of enzyme, the specific substrate used, the temperature of the experiment, and the buffering species used in the experiment. In using enzymes for analysis, it is not necessary for the reaction be carried out at the pH optimum for activity, or even at a pH at which the enzyme is most stable. However, it is critical to maintain a fixed pH during the reaction (i.e. use buffer) and to use the same pH in all studies to be compared.

2.3.3 Inhibitors

An enzyme inhibitor is a compound which, when present in an enzyme-catalyzed reaction medium, decreases the enzyme activity. Enzyme inhibitors can be categorized as irreversible or reversible inhibitors. Enzyme inhibitors include inorganic ions, such as Pb$^{2+}$ or Hg$^{2+}$ that can react with sulphydryl groups to inactivate the enzyme, compounds that resemble substrate, and naturally occurring proteins that specifically bind to enzymes (e.g. protease inhibitors found in legumes).

2.4 Methods of Measurement

For practical enzyme analysis, it is necessary to be familiar with the methods of measurement of the reaction. Any physical or chemical property of the system that relates to
substrate or product concentration can be used to follow an enzyme reaction. A wide variety of methods are available to follow enzyme reactions, including absorbance spectrophotometry, fluorimetry, manometric methods, titration, isotope measurement, and viscosity. An example of the use of spectrophotometry as a method for following enzyme reactions is use of the spectra of the pyridine coenzyme NADH (nicotinamide adenine dinucleotide (reduced form)) and NADPH (nicotinamide adenine dinucleotide phosphate (reduced form)), in which there is a marked change in absorbance at 340 nm upon oxidation/reduction. Many methods depend on the increase or decrease in absorbance at 340 nm when these coenzymes are products or substrates in a coupled reaction.

An example of using several methods to measure the activity of an enzyme is in the assay of α-amylase activity. \( \alpha \)-Amylase cleaves starch at α-1,4 linkages in starch and is an endoenzyme. This reaction can be monitored by a number of methods, including reduction in viscosity, increase in reducing groups upon hydrolysis, reduction in color of the starch–iodine complex, and polarimetry. However, it is difficult to differentiate between the activities of α-amylase and β-amylase using a single assay. β-Amylase cleaves maltose from the nonreducing end of starch. While a marked decrease in viscosity of starch or reduction in iodine color would be expected to occur because of α-amylase activity, β-amylase can also cause changes in viscosity and iodine color if in high concentration. In order to establish whether α-amylase or β-amylase is being measured, the change in the number of reducing groups must be determined as a basis of comparison. Because α-amylase is an endoenzyme, hydrolysis of a few bonds near the center of the polymeric substrate will cause a marked decrease in viscosity, while hydrolysis of an equal number of bonds by the exoenzyme β-amylase will have little effect on viscosity. If options are available in methodology, a method should be selected that is able to monitor the reaction continuously, is sensitive, and is specific for the enzyme-catalyzed reaction.

### 2.4.1 Coupled Reactions

Enzymes can be used in assays via coupled reactions. **Coupled reactions** involve the use of two or more enzyme reactions so that a substrate or product concentration can be readily followed. In using a coupled reaction, there is a *measuring reaction* (Equation 3) and a *indicator reaction* (Equation 4). For example

\[
\begin{align*}
S_1 & \underset{E_1}{\longrightarrow} P_1 & \text{(3)} \\
P_1 & \underset{E_2}{\longrightarrow} P_2 & \text{(4)}
\end{align*}
\]

The role of the indicating enzyme (E2) is to produce P2, which is readily measurable, and hence an indication of the amount of P1 produced by E1. Alternatively, the same sequence can be used in measuring S1, the substrate for E1. When a coupled reaction is used to measure the activity of an enzyme (e.g. E1 above), it is critical that the indicating enzyme E2 not be rate limiting in the reaction sequence. The measuring reaction must always be rate determining. Consequently, E2 activity should be much greater than E1 activity for an effective assay. Coupled enzyme reactions can have problems with respect to pH of the system if the pH optima of the coupled enzymes are quite different. It may be necessary to allow the first reaction (e.g. the measuring reaction catalyzed by E1 above) to proceed for a time, and then arrest the reaction by heating, to denature E1. The pH is adjusted, the indicating enzyme E2 added, and the reaction completed. If an end-point method is used with a coupled system, the requirements for pH compatibility are not as stringent as for a rate assay, because an extended time period can be used to allow the reaction sequence to go to completion.

### 2.5 Applications

As described above, certain information is needed prior to using enzyme assays analytically. In general, knowledge of \( K_m \), the time course of the reaction, the enzyme specificity for substrate, the pH optimum and pH stability of the enzyme, and the effects of temperature on the reaction and stability of the enzyme are desirable. This information is available from the literature in many instances. However, a few preliminary experiments may be necessary, especially in the case of experiments in which velocities are measured. A time course to establish linearity of product formation or substrate consumption in the reaction is a necessity. An experiment to show linearity of velocity of the enzyme reaction to enzyme concentration is recommended.

#### 2.5.1 Substrate Assays

The following is not an extensive compendium of methods for the measurement of food components by enzymatic analysis. Instead, it is meant to be representative of the types of analyses possible. The reader can consult handbooks published by the manufacturers of enzyme kits, for example, Boehringer-Mannheim, the review article by Whitaker, and the series by Bergmeyer for a more comprehensive guide to enzyme methods applicable to foods.

#### 2.5.1.1 Sample Preparation

Because of the specificity of enzymes, sample preparation prior to enzyme analysis is often minimal, and may involve only extraction and removal of solids by filtration or centrifugation.
Table 1  Analytical determination of compounds that serve as substrates. (Adapted from Whitaker[3])

Nevertheless, owing to the wide variety of foods that might be encountered by the analyst using enzyme assays, a check should be made of the extraction and enzyme reaction steps by standard addition of known amounts of analyte to the food and extract, and measurement of recovery of that standard. If the standard additions are fully recovered, this is a positive indication that the extraction is adequate, that the sample does not contain interfering substances that require removal prior to the enzymatic analysis. In some cases, interfering substances are present but can be readily removed by precipitation or adsorption. For example, polyvinylpolypyrrolidone (PVPP) powder can be used to decolorize juices or red wines. With the advent of small syringe minicolumns (e.g. C₁₈, silica, and ion-exchange cartridges), it is also relatively easy and fast to attain group separations to remove interfering substances from a sample extract.

2.5.1.2 Total Change/End-point Methods While substrate concentrations can be determined in rate assays when the reaction is first order with respect to substrate concentration, ([S] ≪ Kₘ), substrate concentration can
also be determined by the total change or end-point method. In this method, the enzyme-catalyzed reaction is allowed to go to completion, so that concentration of product can be measured and directly related to substrate. An example of such a system is the measurement of glucose using glucose oxidase and peroxidase, as described below.

In some cases, an equilibrium is established in an end-point method, in which there is a significant amount of substrate remaining in equilibrium with the product. In these cases, the equilibrium can be altered. For example, in cases in which a proton-yielding reaction is used, alkaline conditions (increase in pH) can be used. Trapping agents can also be used, in which the product is effectively removed from the reaction, and the reaction goes to completion by mass action. Examples include the trapping of ketones and aldehydes by hydrazine. In this way, the product is continually removed and the reaction pulled to completion. The equilibrium can also be displaced by increasing cofactor or coenzyme concentration.

Another means of driving a reaction to completion is a regenerating system. For example, in the measurement of glutamate, with the aid of glutamate dehydrogenase, and (8):

\[
\text{glutamate + NAD (nicotinamide adenine dinucleotide) dehydrogenase} + H_2O \rightleftharpoons \alpha\text{-ketoglutarate} + NADH + \text{NH}_4^+ \tag{5}
\]

\[
\text{pyruvate + NADH + H}^+ \rightleftharpoons \text{NAD}^+ + \text{lactate} \tag{6}
\]

In this system, NADH is recycled to NAD\(^+\) via lactate dehydrogenase until all the glutamate to be measured is consumed. The reaction is stopped by heating to denature the enzymes present, a second aliquot of glutamate dehydrogenase and NADH is added, and the \(\alpha\)-ketoglutarate (equivalent to the original glutamate) measured via decrease in absorbance at 340 nm. An example in which the same equilibrium is displaced in the measurement of glutamate is given by Equations (7) and (8):

\[
\text{glutamate + NAD + H}_2O \rightleftharpoons \alpha\text{-ketoglutarate} + NADH + \text{NH}_4^+ \tag{7}
\]

\[
\text{NADH + INT} \rightarrow \text{NAD}^+ + \text{formazan} \tag{8}
\]

Iodonitrotetrazolium chloride (INT) is a trapping reagent for the NADH product of the glutamate dehydrogenase-catalyzed reaction. The formazan formed is measurable colorimetrically at 492 nm.

### 2.5.1.3 Measurement of Sulfite

Sulfite is a food additive that can be measured by several techniques, including titration, distillation followed by titration, gas chromatography, and colorimetric analysis. Sulfite can also be specifically oxidized to sulfate by the commercially available enzyme sulfite oxidase (SO); see Equation (9):

\[
\text{SO}_3^{2-} + O_2 + H_2O \rightarrow \text{SO}_4^{2-} + H_2O_2 \tag{9}
\]

The \(H_2O_2\) product can be measured by several methods including use of the enzyme NADH-peroxidase (Equation 10):

\[
\text{H}_2\text{O}_2 + \text{NADH} + H^+ \xrightarrow{\text{NADH-peroxidase}} 2\text{H}_2\text{O} + \text{NAD}^+ \tag{10}
\]

The amount of sulfite in the system is equal to the NADH oxidized, which is determined by a decrease in absorbance at 340 nm. Ascorbic acid can interfere with the assay, but can be removed by using ascorbic acid oxidase.\(^5\)

### 2.5.1.4 Colorimetric Determination of Glucose

The combination of enzymes glucose oxidase and peroxidase can be used specifically to measure glucose in a food system. Glucose is preferentially oxidized by glucose oxidase to produce gluconolactone and hydrogen peroxide. The hydrogen peroxide plus \(o\)-dianisidine in the presence of peroxidase produces a yellow color that absorbs at 420 nm (Equations 11 and 12). This assay is normally carried out as an end-point assay. There is stoichiometry between the color formed and the amount of glucose in the extract, which is established with a standard curve. Because glucose oxidase is quite specific for glucose, it is a useful tool in determining the amount of glucose in the presence of other reducing sugars.

\[
\beta\text{-D-glucose} + O_2 \xrightarrow{\text{glucose oxidase}} \delta\text{-gluconolactone} + H_2O_2 \tag{11}
\]

\[
\text{H}_2\text{O}_2 + o\text{-dianisidine} \xrightarrow{\text{peroxidase}} \text{H}_2\text{O} + \text{oxidized dye (colored)} \tag{12}
\]

### 2.5.1.5 Starch/Dextrin Content

Starch and dextrins can be determined by enzymatic hydrolysis using amyloglucosidase, an enzyme that cleaves \(\alpha\)-1,4 and \(\alpha\)-1,6 bonds of starch, glycogen, and dextrins, liberating glucose. The glucose formed can be subsequently determined enzymatically. Glucose can be determined by the previously described colorimetric method, in which glucose is oxidized by glucose oxidase and coupled to
a colored dye via reaction of the glucose oxidase product (hydrogen peroxide) with peroxidase. An alternative method of measuring glucose is by coupling hexokinase (HK) and glucose-6-phosphate dehydrogenase (G6PDH) reactions (Equations 13 and 14):

\[
glucose + ATP (adensine triphosphate) \xrightarrow{HK} glucose-6-phosphate + ADP (adensine diphosphate) \tag{13}
\]

\[
glucose-6-phosphate + NADP^+ \xrightarrow{G6PD} 6-phosphogluconate + NADPH + H^+ \tag{14}
\]

The amount of NADPH formed is measured by absorbance at 340 nm and is a stoichiometric measure of the glucose originating in the dextrin or starch hydrolyzed by amylloglucosidase. The amount of starch determined by this method is calculated using Equation (15):

\[
c = \frac{V \cdot MW \cdot \Delta A_{340} \cdot v \cdot b \cdot 1000}{1000} \tag{15}
\]

where \(c\) is the starch in sample solution (g L\(^{-1}\)), \(V\) is the volume (mL) of reaction mixture, \(MW\) is the molecular weight of starch (because this method measures glucose derived from starch use 162.1, \(MW_{\text{glucose}} = MW_{\text{water}}\)), \(\varepsilon\) is the absorption coefficient of NADPH at 340 nm (6.3 L mmol\(^{-1}\) cm\(^{-1}\)), \(b\) is the light pathlength of cuvette (1 cm), \(v\) is the volume of sample (mL), and \(\Delta A_{340}\) is the absorbance at 340 nm (\(=A_{340,\text{sample}} - A_{340,\text{reagent blank}}\)).

Note that HK catalyzes the phosphorylation of fructose as well as glucose. The determination of glucose is specific because of the specificity of the second reaction catalyzed by G6PDH, in which glucose-6-phosphate is the substrate (Equation 14).

This assay sequence can be used to detect the dextrins of corn syrup used to sweeten a fruit juice product. A second assay would be needed, however, without treatment with amylloglucosidase, to account for the glucose in the product. The glucose determined in that assay would be subtracted from the result of the assay in which amylloglucosidase is used.

The same HK, G6PDH sequence used to measure glucose can also be used to measure other carbohydrates in foods. For example, lactose and sucrose can be determined via specific hydrolysis of these disaccharides by β-galactosidase and invertase respectively, followed by the use of the earlier described HK, G6PDH sequence.

\subsection{2.5.1.6 Determination of D-Malic Acid in Apple Juice}

Two stereo isomeric forms of malic acid exist. L-Malic acid occurs naturally, while the D form is normally not found in nature. Synthetically produced malic acid is a mixture of these two isomers. Consequently, synthetic malic acid can be detected by a determination of D-malic acid. One means of detecting the malic acid is through the use of the enzyme decarboxylating D-malate dehydrogenase (DMD). Decarboxylating DMD catalyzes the conversion of D-malic acid according to Equation (16):

\[
d\text{-malic acid} + \text{NAD}^+ + H^+ \xrightarrow{DMD} \text{pyruvate} + \text{CO}_2 + \text{NADH} \tag{16}
\]

The reaction can be followed by the measurement of NADH photometrically. Because CO\(_2\) is a product of this reaction and escapes, the equilibrium of the reaction lies to the right and the process is irreversible. This assay is of value because the addition of synthetic D/L-malic acid can be used to increase the acid content of apple juice and apple juice products illegally.

ATP bioluminescence is based on the reaction catalyzed by the enzyme luciferase from the North American firefly (\textit{Photinus pyralis}). The chemical energy of ATP drives the luciferase-catalyzed oxidative decarboxylation of lucifin with the resultant emission of one photon of light for each ATP (Equation 17).

\[
luciferin + ATP + O_2 \xrightarrow{\text{luciferase}} \text{decarboxyluluciferin} + \text{CO}_2 + \text{AMP} + \text{PPi} \tag{17}
\]

Thus, a measure of the amount of ATP present is achieved. Because living cells contain ATP this reaction can be used as a means of detecting biomass including microbes. The hygiene status of food contact surfaces as a measure of sanitation and cleaning is a critical quality assurance function, because microbes can be a direct risk. In addition, food product residues can provide nutrients that allow initially small numbers of microbes to grow, compromising the next batch of food processed through the equipment. Because ATP is present in living cells including the food product residue, ATP luminescence can be used to monitor the cleaning, the removal of food residue, and the sanitizing of food equipment to destroy microorganisms. Swab sampling of surfaces followed by ATP luminescence assay has been commercialized and the procedure can be completed in less than one minute to assess cleaning efficiency and remedial action can be taken. Microbial contamination of food product can also be measured by this reaction if ATP of the food itself is eliminated. The use of ATPase prior to extraction of microbial cell ATP and measuring the liberated ATP has been shown to be an effective means of sterility testing in fruit juice.
2.5.2 Enzymes as Preparative Tools

Enzymes can be used in a number of ways to prepare food samples for analyses. A good example of the preparative use of enzymes in food analysis is in the determination of fiber in foods. Dietary fiber is made up of plant polysaccharides and lignin that are not digested by human enzymes. Dietary fiber can be estimated by selectively solubilizing digestible carbohydrates, lipids and proteins by a combination of chemical and enzyme treatment. Enzymes used for this purpose include amylases to solubilize starch and proteases to digest proteins. Undigested materials are collected, dried and the residue weighed, ashed and the weight of the ash subtracted from the residue weight. Alternatively, after solubilization of digestible materials by enzyme treatment, fiber components in the residue are acid hydrolyzed, the resulting monosaccharides are measured, and the sum of the monosaccharides in the hydrolysate represents fiber. An example of the latter approach is that of Englyst and Cummings.\(^8\) In this method, samples are mixed with dimethylsulfoxide by addition of ethanol. The insoluble residue (fiber) is digested with pancreatin (a pancreatic preparation that contains several enzymes, including amylase, proteases and lipase) and pullulanase, which cleaves α-1,6 linkages in starch. Starch and protein are digested with pancreatin (a pancreatic preparation that contains several enzymes, including amylase, proteases and lipase) and pullulanase, which cleaves α-1,6 linkages in starch. Starch hydrolysis is completed by adding α-amylase. Undigested carbohydrate is precipitated by addition of ethanol. The insoluble residue (fiber) is collected by centrifugation, washed with ethanol and acetone, and dried. The residue is acid hydrolyzed and then neutral sugars are measured by gas chromatography and uronic acids (from pectin) are measured colorimetrically. A general problem encountered in the analysis of fiber by treatment of samples with polysaccharide-hydrolyzing enzymes, is that some microbial preparations (e.g. amyl-glucosidase) may be contaminated with β-glucanase (cellulase) resulting in an underestimation of cellulose in the fiber.\(^9\)

The polymerase chain reaction (PCR) is an established DNA amplification methodology that takes advantage of a heat-stable DNA polymerase as a preparative tool. The technique uses three steps: DNA preparation, DNA amplification, and DNA detection. In this process DNA is released from bacteria via lysis after a pre-enrichment step, a targeted DNA region is cyclically amplified with the polymerase using specific primers and the sample DNA is separated by electrophoresis and detected. PCR has the advantage of quickly and specifically identifying pathogenic microbes. For example, PCR using four sets of oligonucleotide primers for target genes for enterotoxigenic, enteroinvasive, enterohemorrhagic and total \textit{Escherichia coli} has been used for detection of fewer than \(10^2–10^3\) cells per gram of these types of microbe in artificially contaminated ground beef.\(^10\) The protocol, including pre-enrichment steps, takes less than 1.5 days, compared to enrichment and selective media methods that take 4–5 days.\(^11\)

2.5.3 Enzyme Activity Assays

2.5.3.1 Peroxidase Activity  Peroxidase is found in most plant materials and is reasonably stable to heat. A heat treatment that will destroy all peroxidase activity in a plant material is usually considered to be more than adequate to destroy other enzymes and most microbes present. In vegetable processing, therefore, the adequacy of the blanching process can be monitored by following the disappearance of peroxidase activity.\(^12\) Peroxidase catalyzes the oxidation of guaiacol (colorless) in the presence of hydrogen peroxide to form tetraguaiacol (yellow brown) and water (Equation 18). Tetraguaiacol has an absorbance maximum around 450 nm. Increase in absorbance at 450 nm can be used to determine the activity of peroxidase in the reaction mixture.

\[
\text{H}_2\text{O}_2 + \text{guaiacol} \xrightarrow{\text{peroxidase}} \text{tetraguaiacol} + \text{H}_2\text{O} \quad (\text{colored})
\]

2.5.3.2 Lipoxygenase  It has been pointed out that lipoxygenase may be a more appropriate enzyme to measure the adequacy of blanching of vegetables than peroxidase.\(^13\) Lipoxygenase refers to a group of enzymes that catalyze the oxidation by molecular oxygen of fatty acids containing a cis,cis,1,4-pentadiene system, producing conjugated hydroperoxide derivatives (Equation 19):

\[
\begin{align*}
\text{O} & \quad \text{(conjugated)} \\
\text{O} & \quad \text{(tetraguaiacol)}
\end{align*}
\]

A variety of methods can be used to measure lipoxygenase activity in plant extracts. The reaction can be followed by measuring loss of fatty acid substrate, oxygen uptake, occurrence of the conjugated diene at 234 nm, or the oxidation of a cosubstrate such as carotene.\(^14\) All these methods have been used and each has its advantages. The oxygen electrode method is widely used and replaces the more cumbersome manometric method. The electrode method is rapid and sensitive and gives continuous recording. It is normally the method of choice for crude extracts, but secondary reactions involving oxidation must be corrected for or eliminated. Zhang et al. have reported the adaptation of the O\(_2\) electrode method for the assay of lipoxygenase in green bean homogenates without extraction.\(^15\) Owing to the rapidity of the method (<3 min including the homogenization),
on-line process control, using lipoxygenase activity as a control parameter for optimization of blanching of green beans, is a real possibility. The formation of conjugated diene fatty acids with a chromophore at 234 nm can be followed continuously. However, optically clear mixtures are necessary. Bleaching of carotenoids has also been used as a measure of lipoxygenase activity. However, the stoichiometry of this method is uncertain and all lipoxygenases do not have equal carotenoid bleaching activity. Williams et al. have developed a semiquantitative spot test assay for lipoxygenase in which \( \Gamma^- \) is oxidized to \( \Gamma_2 \) in the presence of the linoleic acid hydroperoxide product and the \( \Gamma_2 \) is detected as an iodine–starch complex.\(^{(15)}\)

2.5.3.3 Alkaline Phosphatase Assay  
Alkaline phosphatase is a relatively heat-stable enzyme found in raw milk. The thermal stability of alkaline phosphatase in milk is greater than the nonspore-forming microbial pathogens present in milk. The phosphatase assay is applied to dairy products to determine whether pasteurization has been done properly, and to detect the addition of raw milk to pasteurized milk. The common phosphatase test is based on the phosphatase-catalyzed hydrolysis of disodium phenyl phosphate liberating phenol.\(^{(18)}\) The phenol product is measured colorimetrically after reaction with CQC (2,6-dichloroquinonechloroimide) to form a blue indophenol. The indophenol is extracted into \( n \)-butanol and measured at 650 nm. This is an example of a physical separation of product to allow the ready measurement of an enzyme reaction. A fluorimetric assay has been suggested and has been commercialized for measurement of alkaline phosphatase, in which the rate of fluorophore production can be monitored directly without butanol extraction used to measure indophenol when phenylphosphate is used as substrate.\(^{(59)}\) The fluorimetric assay was shown to give greater repeatability compared to the standard assay, in which phenylphosphate is used as substrate and was capable of detecting 0.05% raw milk in a pasteurized milk sample.

2.5.3.4 \( \alpha \)-Amylase Activity  
Amylase activity in malt is a critical quality parameter. The amylase activity in malt is often referred to as diastatic power and refers to the production of reducing sugars by the action of \( \alpha \)- and \( \beta \)-amylases on starch. The measurement of diastatic power involves the digestion of soluble starch with a malt infusion (extract) and following the increase in reducing substances by measuring reduction of Fehling’s solution or ferricyanide. Specifically measuring \( \alpha \)-amylase activity (often referred to as dextrinizing activity) in malt is more complicated and is based on using a limit dextrin as substrate. Limit dextrin is prepared by action of \( \beta \)-amylase (free of \( \alpha \)-amylase activity) on soluble starch. The \( \beta \)-amylase clips maltose units off the nonreducing end of the starch molecule until an \( \alpha \)-1,6-branch point is encountered. The resulting product is a \( \beta \)-limit dextrin that serves as the substrate for the endo-cleaving \( \alpha \)-amylase. A malt infusion is added to the previously prepared limit dextrin substrate and aliquots are removed periodically to a solution of dilute iodine. The \( \alpha \)-amylase activity is measured by the changed color of the starch–iodine complex in the presence of excess \( \beta \)-amylase used to prepare the limit dextrin. The color is compared to a colored disc on a comparator. This is continued until the color is matched to a color on a comparator. The time to reach that color is the dextrinizing time and is a measure of \( \alpha \)-amylase activity, a shorter time representing a more active preparation.

Because \( \alpha \)-amylase is an endoenzyme, when it acts on a starch paste the viscosity of the paste is dramatically reduced, greatly influencing flour quality. Consequently, \( \alpha \)-amylase activity is of great importance in whole wheat. Wheat normally has small amounts of \( \alpha \)-amylase activity, but when wetted in the field, preharvest sprouting (pregermination) can occur, with a dramatic increase in \( \alpha \)-amylase activity. Preharvest sprouting cannot be easily detected visually, so measurement of \( \alpha \)-amylase activity can be used as a sensitive estimate of preharvest sprouting. The falling number method is a procedure in which ground wheat is heated with water to form a paste, and the time it takes for a plunger to fall through the paste is recorded.\(^{(20)}\) Accordingly, the time in seconds (the falling number) is inversely related to the \( \alpha \)-amylase activity and the degree of preharvest sprouting. This method of measuring enzyme activity is a good example of using change in physical property of a substrate as a means of estimation of enzyme activity.

2.5.3.5 Rennet Activity  
Rennet, an extract of bovine stomach, is used as a coagulating agent in cheese manufacture. Most rennet activity tests are based on noting the ability of a preparation to coagulate milk. For example, 12% nonfat dry milk is dispersed in a 10-mM calcium chloride solution and warmed to 35 °C. An aliquot of the rennet preparation is added and the time of milk clotting is observed visually. The activity of the preparation is calculated in relation to a standard rennet. As opposed to coagulation ability, rennet preparations can also be evaluated for proteolytic activity by measuring the release of a dye from azocasein (casein to which a dye has been covalently attached). In this assay, the rennet preparation is incubated with 1% azocasein. After the reaction period, the reaction is stopped by adding trichloroacetic acid. The trichloroacetic acid precipitates the protein that is not hydrolyzed. The small fragments of colored azocasein produced by the hydrolysis of the rennet are left in solution and absorbance is read at
345 nm. This assay is based on the increase in solubility of a substrate upon cleavage by an enzyme.

2.5.3.6 Meat Cooking Indicators Concerns regarding the safety of food products has prompted the development of rapid accurate methods for verification of proper processing of food products. In the case of measuring microbiological safety of meat products, a number of enzymes endogenous to the meat have been examined as indicators of adequate cooking to inactivate food pathogens. Several bovine muscle enzymes have been studied as potential indicators of adequate heating. This work compared the inactivation of the food pathogens *E. coli* O157: H7 and *Salmonella senftenberg* in ground beef to endogenous muscle enzymes acid phosphatase, lactate dehydrogenase, peroxidase, phosphoglycerate mutase, glyceraldehyde-3-phosphate dehydrogenase, and triose-phosphate isomerase. The temperature dependence of the inactivation rate constant of the triose-phosphate isomerase was similar to those of the two pathogens, suggesting that this enzyme could be used as an endogenous time–temperature indicator in beef products.

2.5.4 Biosensors/Immobilized Enzymes

The use of immobilized enzymes as analytical tools is currently receiving increased attention. An immobilized enzyme in concert with a sensing device is an example of a biosensor. A biosensor is a device composed of a biological sensing element (e.g. enzyme, antibody, etc.) coupled to a suitable transducer (e.g. optical, electrochemical, etc.). Immobilized enzymes, because of their stability and ease of removal from the reaction, can be used repeatedly, thus eliminating a major cost in enzyme assays. The most widely used enzyme electrode is the glucose electrode in which glucose oxidase is combined with an oxygen electrode to determine glucose concentration. When the electrode is put into a glucose solution, the glucose diffuses into the membrane where it is converted to gluconolactone by glucose oxidase with the uptake of oxygen. The oxygen uptake is a measure of the glucose concentration. Glucose can also be measured by the action of glucose oxidase with the detection of hydrogen peroxide, in which the hydrogen peroxide is detected amperometrically at a polarized electrode. A large number of enzyme electrodes (biosensors) have been reported in the literature. For example, a glycerol sensor, in which glycerol dehydrogenase was immobilized, has been developed for the determination of glycerol in wine. NADH produced by the enzyme was monitored with a platinum electrode. Immobilized glucose oxidase has been combined with glucoamylase and an oxygen electrode in a flow injection analysis (FIA) system for the evaluation of starch damage in wheat flour. Starch damage is a measure of intensity of milling, and in some cases results in poor-quality finished products. Starch damage was estimated after pretreatment of flour slurries with fungal α-amylase for 15 min and the resulting filtrate was injected into the FIA system containing the immobilized enzymes. The method was demonstrated to give results in 20 min that agreed well with time-consuming traditional methods.

3 IMMUNOLOGY

3.1 Overview

Immunological methods are useful in food analysis because of their specificity and sensitivity. Immunochemical techniques can be used to analyze individual components to relate composition to food quality, to detect contaminants in foods and to monitor processing.

Immunological techniques are dependent on the interactions of antibodies with antigens. Antibodies are serum proteins (immunoglobulins) produced by animals in response to immunization with compounds (antigens) which are foreign to the animal. A wide range of compounds, including polysaccharides and proteins, can serve as antigens. Antibodies produced in response to an antigen have the ability specifically to bind with that antigen due to combining sites on the immunoglobulin with a portion of the antibody. That portion is the antigenic determinant. The specificity of combination between antibody and antigen is similar to that observed in other protein–ligand interactions such as enzyme–substrate.

The size of antigenic determinants has been estimated to be no larger than six or seven sugar residues. A protein would be expected to have many antigenic determinants, resulting in the production of a number of antibodies each with a specificity for a particular antigenic site on the protein. Haptens are small molecules (less than 1000 Da) that are unable to cause the production of antibodies when injected into an animal, and must be linked to a protein such as bovine serum albumin to elicit antibodies to that small molecule. Antibodies made against the conjugate will bind to hapten found in samples.

An immunochemical assay is a procedure in which the noncovalent binding between an antigen and antibody is used as the mode of specificity for the analysis. There are a number of ways to observe or monitor the antibody–antigen noncovalent interaction.

3.2 Methods

3.2.1 Agglutination

The ability of immunoglobulins to bind more than one ligand enables antibodies to agglutinate cells or other
particles that have multiple antigens on their surface. Agglutination can be used as an indirect technique for determining antigens. A series of dilutions of sample to be tested is made into tubes to which a fixed number of red blood cells or latex particles coated with antigen (or antibody) and antibody preparation are added. The particle-bound antigen competes with the antigen in the sample for the antibody. The settling pattern of the cells or particles is observed and antigen amount is estimated based on noting which sample dilution has caused agglutination in comparison to a series of known amounts of antigen.

### 3.2.2 Immunodiffusion

A number of immunochemical methods have been developed that use gels as media for the precipitation of antibody–antigen complexes. Agar or agarose gels are usually used for these methods, since the opaque antibody–antigen precipitate formed can be easily distinguished from the translucent background. Immunodiffusion methods are divided into single and double immunodiffusion techniques.

In most single immunodiffusion techniques, the antigen is allowed to diffuse into a gel in which antibodies have been dispersed. The antigen may be added to the top of a tube containing the gel and allowed to diffuse in a single dimension or it may be added to a well cut into the gel and allowed to diffuse in two dimensions. As the antigen encounters the antibody dispersed in the gel it will form a precipitin band. The precipitation is reversible in an excess of antigen and the precipitin band will appear to move through the gel as it progressively dissociates as more antigen diffuses into the precipitin area and reforms at the diffusing antigen front.

In double diffusion methods, antigens and antibodies are placed in different parts of the gel and allowed to diffuse toward one another. The diffusion can be done in one dimension by placing the antigen and antibody at opposite ends of a tube containing agar or in two dimensions by putting antigens and antibodies in separate wells cut into a layer of agar. The rates of diffusion of the antibody and antigen are dependent on their concentrations and diffusion coefficients, and precipitin bands of different antibody–antigen complexes can occur at different regions of the gel. Therefore, both single and double diffusion techniques have the ability to resolve mixtures of antigens.

Radial immunodiffusion is an example of a single immunodiffusion method that can be used to measure the amount of antigen in a solution and is based on the relationship of rate of diffusion of the antigen to antigen concentration. The antiserum made against the antigen is uniformly dispersed in an agar gel, and dilutions of a known amount of antigen to be measured are placed in wells of the gel. As the antigens diffuse into the gel, precipitin rings are formed around the wells. The diameter of the rings will increase with time due to the continuous dissolution and reformation of precipitate in response to the changing ratio of antibody to antigen. After an appropriate time, the diameters of the precipitin rings are measured and the diameters of the rings around wells of known antigen concentration are plotted as a function of the log of the antigen concentration. This curve is used to estimate the concentrations of the unknown solutions from the diameter of their precipitin rings.

The Ouchterlony method is a double diffusion method in two dimensions and is widely used to determine the relationship of antigens to one another. In this method, the antiserum is added to a well in the center of an agar gel plate and antigen solutions are placed in surrounding wells equidistant from the antiserum well. If two adjacent wells have the identical antigen, the precipitin bands formed between the two wells will fuse into a continuous band of identity. If a mixture of antigens is placed in a well and allowed to diffuse toward a well containing antibodies made against each antigen, several precipitin bands will form due to the independent precipitation of each antibody–antigen complex. If two different antigens are placed in adjacent wells, and allowed to diffuse toward the antibody mixture, the precipitin bands will form a cross in a reaction of nonidentity. If two antigens that share similar or common determinants are placed in adjacent wells they will cross-react and give a reaction of partial identity in which there is a partial fusion of precipitin bands and the formation of a spur extending toward the antigen well with the heterologous antigen. This double diffusion method provides a means of screening samples for multiple antigens and of determining their relationships with other antigens, and is of use in food analysis for determining the origin of food components.

### 3.2.3 Radioimmunoassay

Radioimmunoassays (RIAs) are methods that use an isotopic label on the antigen or antibody as a means of measuring the antibody–antigen complex. The sensitivity of this type of assay is limited primarily by the ability to prepare antibodies or antigen with high specific radioactivity and by the binding constant of the antibody to the antigen.

Most RIAs use labeled antigen and are based on the competition for antibody between radiolabeled antigen and antigen in the sample. As the amount of unlabeled antigen in the sample increases, a smaller amount of radioactivity is bound in the antibody–antigen complex. Thus, after interaction is allowed to take place the antibody–antigen complex is separated from free
antigen and the amount of bound or free radioactivity is determined. By using known amounts of unlabeled antigen, it is possible to construct standard curves by plotting the ratio of bound to free radioactive antigen or the percentage inhibition of bound radioactive antigen as a function of antigen concentration.

### 3.2.4 Enzyme-linked Immunosorbent Assay

Enzyme-linked immunosorbent assay (ELISA) is a solid phase assay in which a reactant (either the antigen or antibody) is adsorbed onto the surface of a test tube or microtiter well, and one of the reacting species (most commonly the antibody) is conjugated with an enzyme. Enzyme immunoassay techniques use the enzymatic conversion of substrate to a colored product as a way of measuring the amount of antigen present. A major advantage of enzyme immunoassay, compared to RIA, is the lack of a requirement to use radioactive compounds. In addition, the sensitivity of an enzyme immunoassay can be greater than RIAs because of the catalytic amplification generated by bound enzyme.

### 3.3 Applications

Applications of immunological methods to food analysis have been largely focused around food safety issues including the detection or measurement of microbes and microbial toxins, pesticide and drug residue analysis, detection of food allergens, estimation of adequate processing for microbial inactivation, and (to a lesser extent), detection of adulteration. The application of immunological techniques to the analysis of food has included the detection of food pathogens and toxins produced by these microbes. Serotyping using immunodiffusion methods has long played a role in identifying bacterial strains and toxins.

The rapid assay of Salmonella species has been accomplished through the use of selective enrichment media and ELISA. [30,31] These methods allow the detection of Salmonella in chicken at less than one microbe per 25 g of chicken sample. The use of latex agglutination in food systems for pathogen detection has been reported by Matar et al. [32] These workers describe the rapid detection of the pathogen Listeria monocytogenes by using antibody to the L. monocytogenes toxin listeriolysin O, coated onto polystyrene-modified latex beads. The method is sensitive and rapid (48 h), whereas culture techniques require more than 4 days.

A major application of immunoassays in foods has been the detection of microbial toxins. A significant effect has been directed at the rapid detection of mycotoxins in foods. Mycotoxins are fungal metabolites that are produced by many species including Aspergillus, Penicillium and Fusarium, and can be found in a number of food materials, including corn, wheat, barley, peanuts, apples, cottonseed, and milk (due to consumption of contaminated feed). Mycotoxins can produce a variety of symptoms in humans and animals, including cancer. Consequently, strict regulations have been established for several of these toxins. Methods of mycotoxin analysis include physical methods such as thin-layer chromatography, gas chromatography and mass spectrometry. Because of interferences in many food matrices, extensive sample clean-up is needed to use these techniques, which are time-consuming and costly.

An alternative to the separation and analysis of mycotoxins is the application of immunological methods. Because mycotoxins are small molecules, they are first conjugated to a carrier protein, such as bovine serum albumin, to be made immunogenic. Antibodies have been made against the major mycotoxins, and both RIAs and ELISA techniques have been successfully applied and commercialized. [33] One particularly interesting method has been described in which antibodies specific for several different mycotoxins, aflatoxin B1, fumonisins B1 and B2 and zearalenone, were immobilized in differentiated lines on nitrocellulose membranes, and a competitive assay was performed in which free mycotoxins from the sample compete with enzyme-labeled mycotoxin for the immobilized antibodies. The amount of color from the bound enzyme is inversely related to the mycotoxin in the sample, and the intensity is assessed using a camera, video monitor and microcomputer. [34]

Contamination of shellfish with paralytic shellfish poisoning (PSP) toxins has little effect on the shellfish; but numbness, tingling, and muscular paralysis or death can result in humans who ingest these toxins. PSP toxin analysis is an example in which a bioassay using a whole animal has been used but can be replaced by an immunoassay. The whole animal assay is simply a measurement of the death of a mouse after intraperitoneal injection of a sample extract. A commercially available competitive ELISA test for PSP toxins using saxitoxin–enzyme conjugate has been systematically tested in mussels and scallops and when compared to the mouse bioassay was found to be 150 times more sensitive. [35]

The detection of economic adulteration of several animal products has been successfully addressed by using immunological methods. The detection of cows’ milk at <1% has been accomplished in goats’ and ewes’ milk and cheeses through the use of competitive ELISA, using antibodies to bovine caseins. [36,37] Similarly, an antiserum against an autoclaved porcine muscle extract was successfully used in a competitive ELISA to detect <1% of pork in cooked beef and mutton. [38]
Food allergies involve abnormal immune responses by certain individuals to specific food proteins. A relatively small number of food sources (peanuts, soybean, milk, tree nuts, fish, crustacea, molluscs and wheat) are responsible for most food allergies. Because avoidance diets are the principal means by which food allergic individuals prevent adverse reactions, the individual must depend on proper labeling and thus depend on the ability of food processors to detect trace amounts of food allergens reliably in food products. A challenge for the food industry is that, in cleaning between products, a residue of allergenic food might be left on processing equipment and be carried into a food product in which the allergenic food is not listed on the food label. Thus, a rapid quality assurance method of detection of allergenic proteins is critical. Mills et al. have devised a dipstick method for the detection of peanut, in which antibody made against conarachin, a major storage protein found in peanuts, is used. Antibodies to purified conarachin are bound to the surface of a paddle-type dipstick, which when immersed into a liquid sample binds conarachin. The dipstick is rinsed and biotinylated anticonarachin is added to “sandwich” the captured peanut protein. The dipstick is rinsed again and immersed into a solution containing avidin–peroxidase conjugate. Avidin strongly binds to the biotin-labeled antibody. Finally the dipstick is rinsed, peroxidase substrate added, and a positive sample is bound to the surface of a paddle-type dipstick, which when immersed into a liquid sample binds conarachin. The dipstick assay detected as little as 0.1% peanut contamination in chocolate with an assay time of <40 min using food samples extracted in aqueous buffer and clarified by centrifugation.

### 3.3.1 Biosensors Based on Immunological Interaction

Biosensors based on the antibody–antigen interaction have been developed and applied to the analysis of a number of food constituents. One type of immunological biosensor that has been commercialized takes advantage of surface plasmon resonance (SPR), which allows direct analysis without labeling of antigen or antibody. SPR occurs when surface plasmon rays are excited at a metal–liquid interface. Light is directed at the surface and reflected from the side not in contact with a liquid sample. The surface in contact with the liquid sample has either antibody or antigen attached, and the formation of the antibody–antigen complex is detected as a change in the SPR signal. This type of biosensor has been used for detection of the pathogen E. coli O157 : H7 and antibiotics in milk, as well as measurement of the vitamins folic acid and biotin. This technology offers specific rapid sensitive analyses and is expected to play a role in food quality assurance systems by providing real-time data in a processing environment.

### 4 ANALYTICAL MICROBIOLOGY

#### 4.1 Overview

It is possible to use microbes to measure many substances that are essential nutrients or inhibitors of microbial metabolic processes. Microbiological assays for the measurement of nutrients are based on the dependence of microbial growth on the presence of limiting amounts of the nutrient being measured. The fundamental methodology in many microbiological assays is similar: addition of the test substance (sample) and growth stimulation or inhibition is measured. The growth response can be measured in several ways including acid production, oxygen uptake, carbon dioxide production, optical density, turbidity, weight, area of colony, or inhibition of spore germination.

An ideal microbe for use in analytical assays should be easily cultivated, nonpathogenic, sensitive to the nutrient to be measured, grow rapidly, and have a readily measurable growth response. Bacteria are most often used as the test organism in microbial assays because of their rapid growth and ease of cultivation.

#### 4.2 Applications

##### 4.2.1 Vitamin Assays

A number of water-soluble vitamins can be readily measured by using the organisms listed in Table 2. In general, these methods entail an aqueous extraction of the food, autoclaving and clarification. The sample and media containing all nutrients except the vitamin being measured are mixed, followed by aseptic inoculation with the appropriate microorganism. Parallel standards containing the limiting vitamin are assayed to prepare a standard

4.2.2 Antibiotic Assays

Antibiotics are used to control diseases in cattle and these antibiotics may enter the food supply via milk or meat. The presence of antibiotics in the food supply is of concern because these compounds can cause allergic reactions, might create an environment favorable to the development of antibiotic resistance in microbes and, in the case of milk, affect starter cultures in the manufacture of fermented dairy products. Approximately 5–10% of the population is hypersensitive to penicillin or other antibiotics and suffers allergic reactions (skin rashes, hives, asthma, anaphylactic shock) at concentrations as low as 1-ppb penicillin. There is also concern that small amounts of antimicrobial agents may significantly shift the resistance patterns in the microbes found in the gastrointestinal tract of man. Antibiotics are also known to interfere with the manufacture of several fermented dairy products. Concentrations of 1 ppb delay starter activity for cheese and yogurt. Antibiotics also decrease the acid and flavor production associated with butter manufacture, reduce the curdling of milk, and cause improper ripening of cheeses.

Testing methods for antibiotic residues in animal products have received significant attention from food industry regulatory agencies and animal production agriculture, and have included use of microbial inhibition assays as well as enzyme inhibition and immunological assays.

The use of Bacillus stearothermophilus var. calidolactis spore suspensions has been extensively used for testing for antibiotics in milk. In one method, a small paper disc is used to wick up a milk sample by capillary action, and the wetted disc is placed on an agar media surface previously seeded with Bacillus spores. The sample is incubated at 64 ± 2°C for ca. 2.5 h during which time well-defined zones of clearing around a positive standard control disc to which penicillin has been added will be seen. The sample is compared to the positive standard. This test can be extended to include treatment of the milk sample with penicillinase followed by the disc assay, allowing identification of samples that contain penicillin or penicillin in combination with nonpenicillin inhibitory substances.

Another method also utilizes Bacillus stearothermophilus var calidolactis, in which a nutrient mixture including bromcresol purple is incubated with a milk sample for 2.5–3 h at 65°C. If no antibiotic is present, acid produced by the microbe causes the bromcresol purple to turn yellow. The presence of an antibiotic prevents acid formation and the purple color of the indicator remains unchanged.

A more equipment-intensive alternative for β-lactam antibiotic analysis is based on the irreversible binding of β-lactams to the cell wall of a microorganism (B. stearothermophilus). A suspension of microbial cells and radiolabeled penicillin are mixed with the sample. If the sample has β-lactam antibiotic present, it will compete with the labeled penicillin for binding sites on the bacterial cell wall. The amount of 14C bound is measured using a gas counter and the reduction of the counts is related to the amount of competing antibiotic in the sample. Counts lower than the control are considered positive. An extension of this analysis is the use of two microorganisms and several radiolabeled antibiotics (both 14Ca and 3H). The combination of more than one microbe binder and two radiolabels allows screening of seven antibiotic types, including tetracycline, penicillin, erythromycin, streptomycin, sulfamethazine, chloramphenicol, and novobiocin. The method can screen for all seven of the antibiotics in 15 min but requires a scintillation counter.

4.2.3 Protein Quality

Protein quality is often assayed using an expensive 28-day rat feeding trial. Microbiological evaluation of protein quality can reduce cost and assay time. Protozoans have received a great deal of attention because they are capable of using insoluble proteins. The heterotrophic protozoan Tetrahymena pyriformis has been extensively explored for use as a test organism for the measurement of protein quality evaluation. T. pyriformis has the same requirement for essential amino acids as for normal rat growth and the ability to digest proteins; thus, growing cultures can degrade intact proteins and the ability of T. pyriformis W to utilize proteins for growth is similar to the growing rat. The technique for biological evaluation of protein with Tetrahymena has been established. Growth of the organism was originally done by counting cell numbers using a hemocytometer with graduated rulings. This method of measuring growth is tedious and is a limitation, and automatic cell counters have been used.
ABBREVIATIONS AND ACRONYMS

ADP: Adenosine Diphosphate
AMP: Adenosine Monophosphate
ATP: Adenosine Triphosphate
CQC: 2,6-Dichloroquinonechloroimide
DMD: D-Malate Dehydrogenase
ELISA: Enzyme-linked Immunosorbent Assay
FIA: Flow Injection Analysis
G6PDH: Glucose-6-phosphate Dehydrogenase
HK: Hexokinase
INT: Iodonitrotetrazolium Chloride
NAD: Nicotinamide Adenine Dinucleotide
NADH: Nicotinamide Adenine Dinucleotide (Reduced Form)
NADP: Nicotinamide Adenine Dinucleotide Phosphate (Oxidized Form)
NADPH: Nicotinamide Adenine Dinucleotide Phosphate (Reduced Form)
PCR: Polymerase Chain Reaction
PPi: Inorganic Pyrophosphate
PSP: Paralytic Shellfish Poisoning
PVPP: Polyvinylpolypyrrolidone
RIA: Radioimmunoassay
SO: Sulfite Oxidase
SPR: Surface Plasmon Resonance

Flavor compounds impart food aroma and taste, which are the major factors influencing consumer’s perception of the quality of food. Understanding the nature of flavor compounds and their effects on human organoleptic responses is important and flavor analysis is an inseparable part of the process.

Analysis of flavor compounds, however, is complicated by several factors. While taste can basically be categorized as being salty, sour, bitter and sweet, the sensations caused by aroma compounds are much more complex.

This results from the presence of numerous volatiles in foods and the ability of humans to differentiate these odorous components. The number of volatile and semivolatile compounds in foods ranges from 50 to 250 compounds in fresh fruits and vegetables to more than double these numbers in thermally processed foods such as roast beef and coffee. The odor-active compounds are usually found in very low concentrations, ranging from a few hundred parts per million (ppm) for strongly flavored food products to less than 10 ppm for weakly flavored foods. In addition, many of these flavor compounds are highly reactive and thermally labile. All of these aspects make flavor analysis a challenging task. Various methods have been developed to cope with the complexity and to resolve practical problems related to food flavors. The first few steps usually involve isolation and concentration of volatiles and semivolatiles from their original food matrix. A number of different techniques, ranging from conventional solvent extraction and distillation to the newly developed direct thermal desorption (DTD) and solid-phase microextraction (SPME) are available for isolating flavors from diverse food systems. Each of these techniques has its own applications with advantages and limitations. No single method will give a flavor isolate truly representative of the flavor profile in the food. Method selection should be based on volatility, thermal stability and reactivity of the flavor compounds and their associated food system. Thereafter separation of the concentrated flavor extract is traditionally conducted by gas chromatography (GC). The combined use of GC with other analytical instruments increases the capacity of basic GC separation. If applicable, pre-GC treatments of flavor extract using liquid chromatography, acid–base separation and chemical trapping of certain volatiles should also be employed to enhance the performance of GC separation. A cyclodextrin-based chiral stationary phase (CSP) is the first choice for separating enantiomers. The follow-up identification of flavor compounds can be carried out by integrating data about retention index (RI) and mass spectrometry (MS) of specific components. However, information obtained by gas chromatography/mass spectrometry (GC/MS) reveals little insight into the actual flavor present in a food system, because many volatiles detected instrumentally contribute little or nothing to the sensory character of a food product. Sensory techniques, coupled with a technique known as gas chromatography/olfactometry (GCO) make it possible to elucidate the relative impacts of various volatiles on the flavor characteristic of a food. CharmAnalysis and aroma extract dilution analysis (AEDA) are two popular methods to measure the potency of flavor components. However, these two methods are inconsistent with psychophysical views. An alternative method named Osme overcomes this problem. It is a quantitative bioassay method used to measure the response to odorants on a time–intensity scale.
quantify volatile compounds, the traditional internal standard method is frequently used, but it is crude and often referred to as "semiquantitative" owing to its inherent limitations. For accurate quantification, a stable isotope dilution assay (IDA) should be used to target specific compounds. This article intends to describe briefly these analytical techniques and discuss their advantages and disadvantages and their applications.

1 INTRODUCTION

Flavor represents a major attribute of food and a deciding factor in the public's measurement of the quality of food. The analysis of flavor is complicated by several factors. The number of flavor compounds in food ranges from 50 to 250 compounds in fresh fruits and vegetables to more than double these numbers in processed foods such as roast beef and coffee. The odor-active compounds are usually found in very low concentrations, ranging from a few hundred ppm for strongly flavored food products to less than 10 ppm for weakly flavored foods. In addition, many of the flavor compounds are highly reactive and thermally labile. All these factors make the analysis of flavor a great challenge in analytical chemistry. This section briefly reviews the common methodology used in the isolation and characterization of flavor compounds in foods. Several monographs have been published on this subject.

2 ISOLATION AND CONCENTRATION TECHNIQUES

Flavor components in food are generally very complex, ranging from 50 to 250 chemicals and even more in thermally processed items. Yet some of the key flavor compounds might exist at extremely low levels beyond the detection threshold of available instruments. On the other hand, human olfactory organs are exceptionally sensitive to odor and may detect as little as 10^{-15} mol of an odorant. It is necessary to isolate and concentrate the analytes from the origin matrix before any analytical process. Great care should be taken before and during isolation and concentration. Flavor compounds differ greatly in physical and chemical properties. Some are very volatile whereas others such as vanillin have a very high boiling point. Some flavors are thermally labile and vulnerable to thermal degradation to produce artifacts. Some are extremely unstable or reactive when separated from food and concentrated for analysis. To liberate the flavor for isolation, some type of crushing, blending, grinding or homogenization is usually applied to the sample. These different processing methods affect the flavor profile to some degree. pH is a factor to be controlled since it influences the GC profile by changing the volatility of flavor compounds. In some cases, enzymes can be used to facilitate the release of odorants. For instance, amylase can be employed in a starch-based food matrix to free the entrapped volatiles. In some situations, enzymes contained in foods need to be inactivated to prevent alteration of the flavor profile during a lengthy isolation process. Inactivation of enzymes in aqueous samples is often realized via the use of heat. However, heat imposes a risk of thermal artifact formation. Another major source of artifacts comes from oxidation during isolation and concentration.

2.1 Direct Solvent Extraction of Aqueous Samples

Direct solvent extraction utilizes the fact that most flavor compounds exhibit substantial solubility in organic solvents. It is the only method that is reasonably efficient in isolating components of both high and low water solubility and is commonly used to extract flavor compounds from beverages, fruit juices and wines and any materials in liquid form or that can be made into liquid form.

The process is accomplished in two steps: extraction and concentration. Separating funnels or commercial liquid/liquid (L/L) extractors may be used for the extraction. Solvent selection is important and the relevant information can be obtained from Weurman and Leary and Reineccius. In general, solvents with a low boiling point are suitable. Nonpolar solvents should be used for samples containing alcohol. Among the commonly used solvents, methylene chloride was found to be satisfactory for general purposes, particularly for flavor compounds with an enolone structure. Other solvents often used include diethyl ether, diethyl ether–pentane mixtures, hydrocarbons and Freons. Safety should be carefully practised during solvent handling owing to the toxicity and potential carcinogenicity of some solvents. Particulate contained in the sample, if any, can be filtered conveniently by a syringe filter such as those recommended for high-performance liquid chromatography (HPLC) sample preparation. Emulsion formation is another frequently encountered problem, particularly in the presence of nonvolatile solutes. Methods such as gentle shaking, centrifugation, slow stirring and pH adjustment may help to curb this pitfall.

A continuous L/L extractor may also be used for extracting flavors from aqueous systems. Continuous-batch L/L extraction generally turns out to be a more efficient method and requires less labor than using a batch separating funnel method but the cost is greater and it requires a longer extraction time.
with liquid carbon dioxide or supercritical carbon dioxide is also included in this category and is discussed in section 2.6.

Following extraction, removal of the solvent or the concentration of the extract is necessary in most cases before chromatographic separation and identification. This is usually carried out by distillation in a special apparatus combined with the use of sodium sulfate. One of the major problems associated with direct solvent extraction is the impurities extracted and concentrated together with the desired analytes. These nonvolatile components come from natural or Maillard pigments, lipids and alkaloids. These same components may leave a residue in the GC injector. Solvent extraction is generally applied only to fat-free foods.

2.2 Steam Distillation of Samples Followed by Solvent Extraction

Distillation followed by solvent extraction is a common sample preparation technique. It takes advantage of the volatility of flavor components and nonvolatility of the major food constituents. Steam distillation typically involves a source of steam, the sample vessel and a series of cold traps. In direct distillation, the sample is normally placed in a round-bottomed flask and dispersed in water. Heat is applied directly to the flask to distill the steam-distillable components. However, overheating should be avoided to prevent scorching of the sample. Stirring may be applied to curb bumping incurred from the possible presence of particulates. An antifoaming agent may be added if foaming poses a potential problem, but this will result in undesirable peaks in later GC analysis. Indirect steam distillation overcomes some of these problems. The sample is not heated directly, so less sample decomposition occurs. The steam comes externally from an electrically heated steam generator or is produced in a round-bottomed flask heated by a mantle. The steam and volatiles are usually condensed in a series of traps cooled with a succession of coolants ranging from ice-water, a slurry of dry ice and acetone or methanol to liquid nitrogen. Compared with the direct technique, indirect steam distillation is more rapid and easier.

Vacuum steam distillation is a choice if sample decomposition remains a concern. In this case, an inert gas should be bled into the system to aid in agitation. A number of cold traps should be fitted in-line to protect the pump from water vapor and the sample from pump oil vapors. The higher boiling components do not distill as efficiently as they do under atmospheric pressure.

The distillate, obtained from distillation, is a very dilute solution containing water, which should be removed using Na₂SO₄ or anhydrous MgSO₄. Extraction of flavors from the distillate with an organic solvent followed by concentration is necessary.

2.3 Simultaneous Steam Distillation and Extraction

As the name simultaneous steam distillation and extraction (SDE) suggests, the distillation and extraction processes needed for sample preparation proceed simultaneously in this technique, which is accomplished via an apparatus specially designed by Likens and Nickerson. Its unique features and related advantages have made this method a popular approach for flavor preparation. Although several modified versions have been made since its origin, the basic principle remains the same. One latest version is shown in Figure 1. A three-necked vertical neck flask (500 ml to 5 L capacity) is filled with the sample slurry to half of its capacity. The sample flask is not heated directly, so less sample decomposition occurs. The steam comes externally from an electrically heated steam generator or is produced in a round-bottomed flask heated by a mantle. The steam and volatiles are usually condensed in a series of traps cooled with a succession of coolants ranging from ice-water, a slurry of dry ice and acetone or methanol to liquid nitrogen. Compared with the direct technique, indirect steam distillation is more rapid and easier.

2.3 Simultaneous Steam Distillation and Extraction

As the name simultaneous steam distillation and extraction (SDE) suggests, the distillation and extraction processes needed for sample preparation proceed simultaneously in this technique, which is accomplished via an apparatus specially designed by Likens and Nickerson. Its unique features and related advantages have made this method a popular approach for flavor preparation. Although several modified versions have been made since its origin, the basic principle remains the same. One latest version is shown in Figure 1. A three-necked vertical neck flask (500 ml to 5 L capacity) is filled with the sample slurry to half of its capacity. The sample flask is not heated directly, so less sample decomposition occurs. The steam comes externally from an electrically heated steam generator or is produced in a round-bottomed flask heated by a mantle. When necessary, agitation is used to prevent bumping and the pH should be adjusted prior to distillation. On the other side of the apparatus, a round or pear-shaped flask of 10–50 mL capacity containing solvent is warmed to vaporize the liquid solvent. Inside the condensers, the vaporized extracting solvent and the sample steam mix

Figure 1 Simultaneous SDE apparatus. (Reprinted from Marsili by courtesy of Marcel Dekker Inc.)
thoroughly and condense under the action of a constant flow of cold water. Consequently, the flavor components from the sample steam are efficiently extracted into the solvent solution.

Various solvents have been used. Schultz et al.\(^{13}\) found hexane to be excellent, except for lower boiling water-soluble compounds, for which diethyl ether was considerably better. Methylene chloride also gained popularity, but pentane–diethyl ether mixtures are currently favored by most researchers. No matter what solvents are used, boiling chips should be added to both flasks to ensure smooth boiling. The SDE process is normally performed for 1–3 h. When it is completed, the system is cooled and the solvent is collected and dried over an agent such as anhydrous sodium sulfate and concentrated by slow distillation or by nitrogen stream flushing.

One major problem found with SDE is thermal degradation. To cope with this problem, vacuum versions of SDE are available to reduce the temperature. However, this might have an adverse effect on flavor recovery\(^9\) and poses difficulty in operation since one must balance the boiling of two flasks, prevent solvent and volatile losses and hold the pressure constant.\(^{10}\) Chung and Cadwallader\(^{14}\) compared SDE under both atmospheric and vacuum conditions for analyzing volatiles from cooked blue crab and found that atmospheric SDE generated more odor-active compounds than vacuum SDE, probably the result of thermal degradation. Besides thermally generated chemicals, other possible sources of artifacts include antifoam agents, vacuum greases on glass joints, contaminated water supplies, solvent impurities and rubber tubing.\(^{11}\) However, steam distillation remains a popular method for flavor isolation owing to its various advantages such as efficiency, the small volume of solvent required, high recovery and a single operation to accomplish extraction and concentration.

2.4 High-vacuum Distillation of Lipid Samples

Lipid samples are those containing a high percentage of lipids, which include vegetable and nut oils, coffee oil, cocoa butter and lard. Solvent extraction of flavor from this type of samples generally should not be conducted owing to the co-extraction of both flavors and lipids. Although either steam distillation followed by solvent extraction or Likens–Nickerson extraction can be employed, the recovery is not satisfactory.\(^{10}\) Since aroma compounds are typically lipophilic, extraction of aroma compounds from these food resources requires different techniques.

High-vacuum distillation appears to be a better choice. It involves the direct transfer of volatiles from a food sample to a cold condenser. This requires very short distances between the condenser and the food sample and the use of high-vacuum systems (\(< 10^{-3} \text{Torr}\)).\(^{11}\) Several designs are available for this purpose.\(^{15,16}\) A falling-film molecular still, designed on the principle of vaporization of the flavor from a heated thin film of the oil under high vacuum, can be used when large amounts of lipid materials are present.\(^{10}\) The most commonly found artifacts via this method are silicone compounds from the high-vacuum grease used on glass joints. The use of silicone O-rings avoids this problem.\(^{15}\)

2.5 Direct Solvent Extraction of Solid Samples

Direct solvent extraction is also a simple and convenient technique for sample preparation, suitable mostly for dry products such as spices, grain flours, chocolate, coffee and other food items of low moisture content. A Soxhlet extractor is often used for the extraction. A portion of the ground sample can be placed in a Soxhlet thimble and extracted with an organic solvent of low boiling point, which can be either diethyl ether or methylene chloride. A series of extraction cycles are necessary to obtain more analytes. At the end, the solvent with extracted analytes should be combined and concentrated. However, nonvolatile compounds such as lipids, caffeine and pigments will also be collected together with the desired analytes. Consequently, techniques such as steam distillation or high-vacuum stripping should be conducted to separate the volatile from the nonvolatile compounds to prevent column clogging if the latter are present in large amounts. Another problem with Soxhlet extractors is the large amount of solvent needed, especially if a large quantity of sample is to be extracted, given the solvent-to-sample ratio needed of around 2:1 by volume, which is generally unfavorable. Large solvent volumes necessitate extreme solvent purity to minimize artifacts or solvent contaminants.\(^{11}\) Column chromatography provides an alternative means to extract solid samples. In this case, the dry solid sample can be ground with an inert bulking material. The blend is then packed into a glass chromatography column and eluted with organic solvent.\(^{17}\)

2.6 Extraction with Liquid or Supercritical Carbon Dioxide

The drive to search for safer and more environmentally friendly extraction and separation methods for flavor analysis resulted in the development of an extraction technique involving liquid or supercritical carbon dioxide as solvent.\(^{18}\) Although extraction with liquid CO\(_2\) and extraction with supercritical CO\(_2\) are two different processes, the principles are the same. Liquid CO\(_2\) extraction takes place at a subcritical state (temperatures <
31 °C, pressures < 74 bar), whereas supercritical extraction proceeds at temperatures above 31 °C and pressures above 74 bar\(^\text{19,20}\). However, supercritical CO\(_2\) has been stated to be a more versatile solvent than liquid CO\(_2\) owing to the wider range of extraction conditions\(^\text{21}\) and therefore presumably a wider range of applications. The physical properties of compressed CO\(_2\) and the required operating conditions confer on the separation technique a number of advantages compared with more conventional extraction and separation processes. First, CO\(_2\) is nontoxic and nonflammable, so it is safer to handle and friendly to the environment. The extracted compounds can be smelled and tasted owing to the absence of organic solvents. The relatively mild temperature and pressures employed in the process reduce the possibility of artifacts produced by thermally labile compounds. In addition, the extracted material is protected from oxidation because of the inert atmosphere in which extraction and separation are conducted. Characteristics of supercritical fluids suitable for extraction purposes and their comparison with conventional methods have been reported by Brogle\(^\text{22}\) and King et al.\(^\text{23}\).

The advantages of liquid or supercritical CO\(_2\) extraction and separation techniques make them ideal for the food and flavor industries and their use has increased during recent years.\(^\text{20,24 - 28}\) They are used regularly for the extraction of hops in the brewing industry, for the decaffeination of coffee and tea, for the dealcoholization of beverages and in the extraction of oleoresins from spices.\(^\text{20,27,28}\) Flavors and fragrances extracted by this method were of higher quality and more true to the source than those from other methods such as solvent extraction, steam distillation, hydrodiffusion and vacuum distillation.\(^\text{29,30}\)

When using supercritical carbon dioxide, it is necessary to balance temperature, pressure and flow rate, which requires complex instrumentation.

### 2.7 Headspace Analysis

Volatile organic compounds contributing to flavor are present in foods in a dynamic equilibrium, which results in the partition of these compounds between the food matrix itself and the gas phase immediately surrounding it. When a food is enclosed in a sealed vessel, its flavor volatiles will partition into the headspace gas of the container, and the many individual compounds comprising the flavor will eventually attain a gas-phase equilibrium concentration. This equilibrium is profoundly influenced by the solubility of the flavor compounds in the food matrix, their vapor pressures, temperatures and many other unpredictable factors such as their enzymatic release from nonvolatile precursors. Static headspace analysis may be chosen when chemical compounds exist as gases at room temperature or have a sufficiently high vapor pressure to evaporate and produce a gas-phase solution. Experimentally, the food sample is placed into a headspace vial that is septum sealed and often warmed to facilitate volatile vaporization. A time period is required to establish equilibrium between the sample phase and the gaseous phase. Subsequently, an aliquot of the headspace gas is withdrawn with a syringe and injected into a gas chromatograph injection port. Since there is no heat involved, the introduction of artifacts is greatly limited. Analyses of volatiles emitted by plants or food products provide data representing fresh flowers, fruits and vegetables as they truly are. In addition, this technique is simple and reliable and remains the cornerstone of many quality assurance/quality control (QA/QC) protocols in the food industry.

However, the static headspace method is also associated with some shortcomings. It has a relative low sensitivity owing to the limited volume of headspace gas that can be injected into the GC column and the low volatility of some flavor constituents. Some organoleptically significant compounds exist at trace levels and may not be detected because of the detection threshold capabilities of GC and GC/MS. Attempts to increase the sensitivity by injecting a larger volume of headspace gas results in loss of chromatographic resolution. Furthermore, oxygen and water vapor often present in the headspace can cause rapid degradation of expensive GC stationary phases and mass spectrometer filaments.

In order to enrich the headspace gas prior to GC analysis, various techniques have been investigated and together they are termed as dynamic headspace analysis since they all involve a means of concentrating headspace aroma volatiles. Broadly, these techniques include cryotrapping, steam distillation, solvent extraction and adsorption (purge and trap). Detailed information about these techniques can be found in Chang et al.\(^\text{31}\), Hartman et al.\(^\text{32}\) and Wampler.\(^\text{33}\)

The physical principle of these sample preparation methods is to strip the volatile flavor compounds from the headspace above the foods by a stream of air or inert gas.\(^\text{34}\) The volatiles are trapped by a collection trap while the purging gas filters through. Different from the static headspace method, where an equilibrium between the sample matrix and the surrounding gaseous phase is established before sampling, in the dynamic headspace method the headspace gas along with the volatile analytes is constantly purged and removed, while the analytes are retained. The process not only causes more of the volatile compounds dispersed in the sample matrix to leave the sample and pass into the trap, but also results in a higher concentration of the analytes available for GC/MS.
analysis. In fact, a dynamic headspace apparatus is usually referred to as a “sample concentrator”. The trapping step may involve adsorption on to a high-surface-area absorbent material (e.g. activated carbon or Tenax® TA) or cold trapping by condensing or freezing the analytes in the trap. The trapped analytes are then desorbed into the GC and GC/MS system for analysis. Figure 2 shows the apparatus used for one of the dynamic headspace techniques called purge and trap.

The dynamic headspace technique does not require the use of solvents. It is an easy sample preparation process and can be automated. In addition, the concentration process increases the sensitivity. Volatiles at parts per billion (ppb) levels can be analyzed routinely and it is possible to analyze components even at the level of parts per trillion (ppt). Furthermore, selectivity and simplicity can be enhanced by using a specific sorbent targeting for specific analytes in the dynamic process.

2.8 Direct Thermal Desorption Methods

DTD is the technique of sparging the volatile compounds from a sample matrix and transferring them directly on to a GC column for analysis.

The development of DTD has gone through several stages. In earlier research, samples were stationed inside a liner with the help of glass wool. The liner was then placed directly in the injection port. The volatiles from the sample were thermally desorbed on to a packed column held at room or subambient temperature followed by GC analysis. This process is associated with a few drawbacks, including finger burn and broad peaks. A later development is called external closed-loop inlet device (ECID), which enables the sample to be heated in its own block instead of inside the injection port. A detailed description is available in Grimm et al. Although ECID has been adapted for use with both packed and capillary columns, its application to capillary columns turned out not to be successful.

The most recent advancement of DTD is called short-path thermal desorption (SPTD). It employs a thermal desorption unit that can be operated either manually or automatically. The device (Figure 3) sits directly on top of the injection port of most GC systems, where it is utilized for the direct desorption of both volatile and semivolatile samples into the GC injection port and column. The sample is placed in a glass-lined stainless-steel tube (GLT) with or without the presence of an adsorbent resin such as Tenax® TA or activated carbon inside the tube. When ready for analysis, the tube is affixed on one end with an injection needle and the other end is screwed into the SPTD unit. During injection, the tube with the needle is released down...
in the heating block of the unit and positioned in proper alignment with the GC injection port (Figure 4). The desorption temperature, time and equilibration are controlled by an electronic console processor. When injection is complete, the flows are readjusted according to the method of analysis. The hinged heating blocks close around the desorption tube, which is heated to the desired temperature to desorb the volatiles from the sample. Under the flow of carrier gas, the desorbed volatiles are purged into the GC injection port and on to the front of the GC column that is held at room or subambient temperature. The volatiles are thus trapped continuously into the GC column until the completion of desorption. Subsequently, GC temperature programming is initiated to volatilize the condensed organics for elution, separation and identification.

Compared with more conventional methods for sample isolation and concentration, DTD is a thermal extraction system of high sensitivity. In addition to being solvent free, the sample requirement is small and tedious sample cleanup is eliminated. More relevant information can be obtained in Hartman et al.\textsuperscript{32} Owing to the "short path" of sample flow, SPTD overcomes the shortcomings of previous desorption systems via the elimination of transfer lines. It provides several unique advantages over other desorption systems. First, it enables the sample to be heated rapidly. Second, the desorbed component can be easily and efficiently transferred into the injection port of the GC system from a GLT, reducing the possible degradation that is frequently encountered in other thermal desorption devices. As a result, artifact production is minimal.

DTD, including SPTD, can be used widely in food analysis\textsuperscript{,}\textsuperscript{32,37} In general, the samples should be solid or semisolid with moisture contents lower than 5% and volatile flavor levels in the range 1–10\textsuperscript{6} ppm (w/w). The moisture content must be low enough so as not to cause freezing and plugging of the GC column when operating in the cryofocusing mode, especially when utilizing narrow-bore capillary columns. Sample sizes in the range 1–500 mg are common in this technique. Before placing the sample inside the tube, sample homogenization is often needed to compensate for flavor variation. This can be accomplished using a laboratory grinding mill with the help of a thermally preconditioned chromatography support (60–80-mesh Chromosorb®).\textsuperscript{32} Samples successfully analyzed for flavors or off-flavors using DTD techniques include spices, coffee, candy, food ingredients, peanuts, vanilla beans, chewing gum, flowers, plant materials, natural products and packaging materials.\textsuperscript{38}

### 2.9 Solid-phase Microextraction

SPME is a newly developed sample extraction and concentration technique used for volatile and semivolatile compound analysis. It is based on the principle of partitioning of organic components between a bulk aqueous or vapor phase and thin polymeric films coated on fused-silica fibers.

The SPME device, as shown in Figure 5, is like a syringe with a spring-loaded plunger and a barrel with a detent to allow the plunger to be held in an extended position...
during the extraction and the injection/desorption period. Inside the barrel there is a stainless-steel needle, which encloses another length of stainless-steel tubing fitted tightly to a short piece of solid-core fused-silica fiber. The bottom part of the fiber is coated with a thin layer of stationary phase. The most commonly used coating polymeric materials include polyacrylate, Carbowax\textsuperscript{16}, divinylbenzene and polydimethylsiloxane. Therefore, there are different SPME fibers coated with these materials for extracting compounds of different size, polarity and volatility.

The sample being analyzed is usually placed in a vial or other suitable container, which is sealed with a septum-type cap to facilitate equilibrium between the headspace and the sample matrix. Before sampling, the fiber should be cleaned because it could possibly be contaminated by aroma chemicals from the air. This can be done by inserting the fiber-attached needle into a GC injection port for a few minutes to desorb thermally any possible contaminant. During sampling, the SPME needle pierces the septum and the fiber is extended out from the needle and immersed directly into an aqueous sample or into the headspace above a liquid or solid sample. Organic compounds in the sample are subsequently adsorbed on the fiber. After a suitable sampling time, the fiber is withdrawn into the needle, which is then removed from the septum and inserted directly into the injection port of a gas chromatograph. Inside the injection port, the absorbed compounds are thermally desorbed and transferred directly to the column for analysis. Care should be taken during the whole process to prevent the brittle fiber from breaking. For high accuracy and precision, full equilibrium is not necessary but a consistent sampling time and other sampling parameters are essential.

The selection of the stationary phase is based on the targeted analytes. Two factors should be considered: polarity of the analytes and volatility and size of the analytes. Polar phases such as polyacrylate and Carbowax\textsuperscript{16} coatings should be chosen for polar analytes. Fibers with a thicker film (100 µm) are better for volatiles, but also can be used for less volatile compounds with a longer extraction time. Porous fibers can also retain small analytes and are ideal for C\textsubscript{2}--C\textsubscript{6} analytes. Thinner film fibers (7 and 30 µm polydimethylsiloxane) are better for larger molecules. Selecting the most appropriate fiber certainly influences the SPME recovery. Sample agitation or stirring, minimizing headspace volume, salt addition and adjustment of pH and temperature are other means of choice for facilitating equilibrium and improving SPME recovery.

The simple SPME requires no solvents or complicated apparatus. Eliminating most drawbacks of conventional extraction methods, it can concentrate volatile and non-volatile compounds in both liquid and gaseous samples for analysis by GC, GC/MS or HPLC. The process can be automated to obtain consistent data of high precision and accuracy. Uniquely, it can be used to extract analytes directly in the field without collecting a sample.

As a result of its various advantages, SPME has quickly gained wide application as an analytical tool in various areas, including flavor analysis, since its commencement. Most recently it was used to analyze the aroma volatiles of a specific rose variety in a weightless environment. It has been successfully used to evaluate flavor and aroma volatiles in fruits,\textsuperscript{39,40} wine\textsuperscript{41} and other beverages.\textsuperscript{42,43} These applications demonstrate the utility of the technique in trapping highly volatile, lower molecular weight and thermally labile flavor compounds where solvent use and distillation methods have proven to be detrimental to product aromagrams.

3 SEPARATION TECHNIQUES

3.1 Pre-gas Chromatography Separation

3.1.1 Liquid Chromatography

The flavor mixtures obtained from food samples usually contain numerous chemical components. This complexity often makes it difficult to identify the flavor components occurring in the system. It is desirable to simplify the mixture to less complex fractions prior to further instrumental analysis. On the other hand, some flavor compounds exist at extremely low levels and large amounts of sample are needed to obtain enough of these trace elements. For the purpose of structure elucidation, the targeted flavor compound needs to be pure and in a relatively large amount in order to conduct nuclear magnetic resonance (NMR) spectroscopy. These aspects necessitate the use of some conventional separation techniques such as column chromatography, alumina fractionation and thin-layer chromatography (TLC) in flavor analysis. Takeoka et al.\textsuperscript{44} used neutral alumina to fractionate the extract from pineapple and identify 26 constituents, including seven sulfur compounds for the first time. In studies of the thermal degradation of thiamine, medium-pressure liquid chromatography based on silica gel was used to preseparate concentrates into different fractions before analysis by high-resolution gas chromatography (HRGC) and HRGC/MS and NMR spectroscopy.\textsuperscript{45} Fractionation by silica gel TLC has found its use in pinpointing off-flavor compounds from spray-dried skim-milk powder\textsuperscript{46} and identifying volatile components in sesame seed oil.\textsuperscript{47} Coulibaly and Jeon\textsuperscript{48} studied various solid-phase materials including activated carbons, C\textsubscript{18} reversed-phase silica, Florisil and silica gel
for isolation of relatively nonvolatile flavor compounds from ultra-high temperature (UHT) milk. The results of their study indicated that the combination of activated carbon and C18 reversed-phase silica is the most effective method for isolating flavor constituents for GC and GC/MS analysis.

The use of HPLC in flavor analysis is largely related to the separation and identification of compounds that are nonvolatile and thermally unstable and usually impart taste perception. These compounds include sugar, nonsugar sweeteners, bitter amino acids and peptides, citrus limonoids and flavonone glycosides. Since HPLC is normally conducted at room temperature, heat-induced artifact formation is greatly reduced. The nature of HPLC also enables it to analyze aqueous samples directly without the need to extract flavor chemicals into an organic phase as is necessary in GC. Fractions obtained via HPLC can be subjected to sensory evaluation given that the solvent used is water or ethanol.

The application of HPLC can be enhanced when it is coupled with GC and GC/MS. The role of HPLC in this powerful analytical system is to fractionate a complex flavor mixture so as to simplify later GC/MS separation and identification, which has to be conducted for each HPLC fraction. This is tedious, but it is necessary, especially for very complex flavor systems. Direct transfer of HPLC fractions into a capillary gas chromatograph designed by Grob et al. made it more convenient to use. To investigate the character impact of compounds in roasted coffee, hundreds of roasted coffee flavor components were fractionated by column chromatography and preparative HPLC, and then subjected to GC, GC/MS and simultaneous GC/sniffing. The sulfur-containing flavor components 3-methyl-2-butene-1-thiol, 1,3-dimercapto-3-methylbutanol and 3-mercaptop-3-methylbutyl formate were found to contribute to the flavor of roasted coffee.

### 3.1.2 Acid–Base Separation

Some flavor compounds exhibit a certain degree of acidity or alkalinity. They can be ionized to be soluble in aqueous solutions. This method takes advantage of the differential solubility of ionized and nonionized species in aqueous and organic solvents. Ionization of ionizable compounds is generally achieved by controlling the pH of the aqueous solvent. This method is normally conducted after obtaining a flavor isolate mixture in order to isolate selectively the compounds of interest.

This method is relatively simple and does not require sophisticated equipment or expensive reagents. After fractionation, the number of flavor constituents is reduced for column analysis, thus allowing more specific column choice and tailoring of GC operating conditions. However, this technique is commonly associated with incomplete separation and poor recovery. To compensate for this, large volumes of solvents and multiple extraction are necessary, which will result in tedious work and dilution of flavor compounds, followed by a greater loss of volatiles during the subsequent step of concentration. Moreover, artifact formation is possible under both alkaline and acidic conditions. Acid–base separation can be combined conveniently together with purge-and-trap techniques for separation purposes. This method modifies the purge-and-trap method to make it more selective; thus it is called the selective purge-and-trap method. It enables flavor chemicals that are minor in quantity but significant in flavor impact to be singled out, thus overcoming the interference by major constituents or by compounds with the same chromatographic properties. This method can be used for the analysis of important flavor volatiles such as pyrazines, pyridines, pyroles, oxazoles and thiazoles. Kuo et al., Joo and Ho, and Yoo and Ho have used this technique for the analysis of volatile pyrazines. In their experiments, as shown in Figure 6, the sample was dispersed in a purge vessel and the suspension was constantly sparged with a stream of nitrogen gas. The purged gas along with the volatiles passed through an HCl trap. Owing to their weakly basic properties, pyrazines were trapped as salts in the acid trap. At the end of purging, the pyrazine-containing acid solution was titrated with NaOH to become basic, and then an alkaline solution was either extracted by a liquid extraction method to isolate the pyrazines or again purged with N2 gas to trap the pyrazines in a Tenax® TA tube. The results proved that this method not only quantifies minor or trace pyrazines from a complex background but also it is much less laborious and time-consuming than other traditional isolation and fractionation methods.

### 3.1.3 Analysis of Aldehydes and Dicarbonyls Using Chemical Trapping Agents

Volatile aldehydes and dicarbonyls, occurring in foods or generated via various mechanisms, pose characteristic...
flavor notes or serve as precursors for the formation of other important flavor compounds. They can play both positive and negative roles by imparting to foods good flavor or off-flavor. The importance of carbonyls also resides in their potential toxicity.⁶⁷

These aspects make the analysis of aldehydes and dicarbonyls in foods necessary. Many methods designed for carbonyl elucidation have been reported. Most of them are based on the concept of using so-called chemical trapping agents, which react with the carbonyl compounds to produce derivatives that can be readily detected. Some of the commonly used agents include 2,4-dinitrophenylhydrazine,⁶⁸ N-benzylethanolamine⁶⁹ and benzoyloxyamine.⁷⁰ One problem in using these derivatization agents is that the strongly acidic and high-temperature conditions required may alter the carbonyl compounds of interest or produce additional carbonyl compounds.⁷¹ Moreover, the formation of both syn and anti forms of aldehyde derivatives is inevitable, making peak identification extremely difficult. Fortunately, a new derivatization method with cysteamine (aminoethanethiol) as the trapping agent was developed recently by Shibamoto et al.⁷² According to Yasuhara and Shibamoto,⁷³ this method has several advantageous features compared with other derivatization methods: (1) only one derivative is formed from one aldehyde; (2) the reaction takes place in very mild conditions, rapidly and with almost quantitative yield; (3) the derivatives, thiazolidines, can be separated perfectly with a fused-silica capillary column and detected selectively with a nitrogen–phosphorus detector; and (4) excess of cysteamine does not interfere with GC analysis. It has been used to analyze volatile carbonyl compounds in foods, beverages, cigarette smoke and automobile exhaust.⁷¹ Many volatile carbonyls at trace levels in the headspace of food samples have also been satisfactorily analyzed by this method.⁷⁴,⁷⁵ A detailed description of the experimental procedure is available in Yasuhara and Shibamoto.⁷⁴

3.2 Gas Chromatography Separations

3.2.1 Standard

In GC, the components of a vaporized sample are separated as a result of partitioning between a mobile gaseous phase and a stationary phase held in a column. The stationary phase in GC is a liquid supported on an inert solid matrix. The excellence of GC has made it one of the most important and widely used column chromatographic methods. The basic process involves the single column separation of a volatile mixture followed by detection at a single “universal” detector. The sample is introduced as a gas at the head of the column and those components that have a finite solubility in the stationary liquid phase distribute themselves between this phase and the gas according to the law of equilibrium. Elution is then accomplished by forcing an inert gas such as helium through the column. The rate of movement of the various components along the column depends on their tendency to dissolve in the stationary liquid phase.

Given its analytical power, it is not surprising that GC has become crucial to the specialized field of aroma investigation. Even in its most essential form, which enables a single column separation of a volatile mixture followed by detection with a single detector, GC can provide several pieces of key information regarding the composition, the elution times, the relative concentrations and the relative volatilities of the various components in the sample mixture under specific operating conditions. However, an obvious limitation is that a basic GC process would fail to reveal the definitive identification, structural and aroma character related to the peaks in a chromatogram. In addition, its ability to separate volatile components is restricted by the complexity of possibly numerous volatile components present. It is not uncommon to have a total component population of hundreds or thousands for a flavor analysis at a target concentration level of as low as 10 ppt.⁷⁶,⁷⁷ Moreover, the actual separation capacity depends on a number of factors, including column efficiency, system performance, column temperature limits and system operating parameters.

3.2.2 Multidimensional

One way to enhance the separation performance by a basic GC process, referred to as single-dimension gas chromatography (SDGC), is to combine different techniques together. A series of hardware configurations are loosely bound under the broad term known as multidimensional gas chromatography (MDGC). According to Bertsch,⁷⁸ two columns of different selectivity and a device to transfer selectively a portion of a chromatographic effluent from one column into another are needed for a technique to qualify as an MDGC technique. However, Wright⁷⁹ favored the notion that in a broader sense the technique can be called MDGC as long as it provides increased qualitative information about peak identification, functionality or other characteristics than could otherwise be provided by SDGC alone. Under this concept, MDGC includes GC combined with MS, Fourier transform infrared (FTIR) spectroscopy, atomic emission detection (AED), inductively coupled plasma (ICP), etc. For the purpose of volatile separation, MDGC usually denotes a two-dimensional GC system. A simplified version of the system is shown in Figure 7. This basic system consists of an injection device, a first column for preliminary separation, a flow-switching device connecting the first column and the second column, a first detector for
profiling the first column separation and a second detector for profiling the second column separation. The first column and detector are often referred to as the precolumn and monitor detector and the second column and detector are called the analytical column and analytical detector.

Among these components, it is the flow-switching device that permits the tremendous increase in separation power of MDGC. It can transfer those portions of the precolumn effluents that are adequately separated or are of no direct interest to the monitor detector, while it directs those portions of the precolumn effluent that are incompletely resolved or are of particular interest into the analytical column for additional separation. By doing this, a number of chromatographic separation difficulties resulting from sample complexity can be overcome. In the system, the precolumn de facto serves as an extension of the sample preparation or sample cleanup steps, so a larger sample volume is allowed for injection compared with SDGC. The peaks appear on the monitor detector as a reference to guide the selective transfer of the effluent of interest to the analytical column/detector, which usually achieves the desired separation. Separation enhancement is positively related to the difference of polarity or selectivity between the precolumn and the analytical column. In many cases, MDGC permits a particular separation to a lower detection limit.

When concentrating the volatile organic compounds from food products, any large amount of potential interfering compounds is inevitably collected and introduced into the GC system. Under SDGC conditions, some of the most significant aroma peaks may be covered up by the surrounding mass of peaks of little or no significance associated with aroma. MDGC can be utilized to overcome this shortcoming. Nishimura was able to identify six new compounds in ginger by AEDA combined with GC and a modified multidimensional GC/MS system. Homatidou et al. used the Freon 11 extraction method and a combination of MDGC and GC/MS to study the volatiles of orange-fleshed Cucumis melo L. var. Cantaloupensis and reported a total profile of identified compounds. In addition, MDGC is often used for enantiomer analysis. Chiral γ-lactones from the raw flavor extract of strawberries and of some commercially available fruit-containing foods and beverages were directly stereoanalyzed by MDGC.

3.2.3 Chiral

Like many other chemical molecules, flavor compounds can also exist as enantiomers. They pose various flavor characteristics of different intensity and with different specificities toward odorant receptors in human subjects. It becomes necessary to differentiate enantiomers partially owing to their distinct impact on flavor characteristics and flavor perception. However, analysis of chiral flavor compounds is not an easy task. Various methods, including chiroptical methods, NMR spectroscopy, electrophoresis and chromatography have been attempted. These methods each have their own advantages and limitations, and thus are suitable only for specific purposes in different disciplines. For the analysis of flavors and fragrances, chromatographic methods are the most suitable. Among the common chromatographic methods, TLC is mainly used for achiral routine analysis whereas HPLC and supercritical fluid chromatography (SFC) offer the advantages of large sample throughput for preparative enantiomer separation.

For analytical purposes, however, GC is the first choice. The key step in the analysis resides in the separation of enantiomeric pairs, which can be accomplished by using the so-called indirect method or direct method. The indirect method requires derivatization of enantiomers to volatile diastereomers. The characteristics and application of a number of derivatization agents were summarized by Schreier et al. This method can be applied to a wide range of chiral compounds such as alcohols, aldehydes, ketones, carboxylic acids, esters and even hydrocarbons. However, the lack of absolute enantiomeric purity of the chiral derivatization agent makes this method inferior to the later developed direct method that is based on the use of a CSP of high enantiomeric purity. According to the separation mechanism, CSP can be divided into three main classes: amide phases, metal complex phases and cyclodextrin phases. They are applicable in different scenarios with their own special features. From the standpoint of flavor analysis, a cyclodextrin-based CSP is the most useful and has become increasingly popular in recent years. Cyclodextrins are cyclic glucans (cyclomaltooligoses) with at least 6–12 D-glucopyranose units in an α,β-γ-cyclodextrins with 6, 7 and 8 glucose units are usually used in analytical chemistry. In recent years, a wide variety of CSPs based on these materials have become available. Almost every chiral flavor
4 IDENTIFICATION OF FLAVOR COMPOUNDS

4.1 Gas Chromatography Retention Indices

In GC, the time elapsed from sample injection to the appearance of a peak maximum is called the retention time (RT). It is the chromatographic property of a chemical, since each compound shows a characteristic emergence on the chromatogram. The RT of an unknown can be compared with that of a standard for identification. However, the RT of a compound is influenced by a number of factors such as column type, carrier gas flow rate and temperature programming conditions. It is almost impossible to reproduce the same RT for the same compound even under the same running conditions. The need to create a standardized system to express GC retention data resulted in the birth of an RI system, known as retention indices or Kovats indices, so called after its designer, Kovats. In this system, the RT of a solute is compared with the RTs of a homologous series of \( n \)-paraffin hydrocarbons and the RI (I) is calculated by Equation (1):

\[
I = 100N + 100(N + 1) \frac{\log t_R(A) - \log t_R(N)}{\log t_R(N + 1) - \log t_R(N)}
\]

where \( N \) and \( N + 1 \) = carbon numbers of paraffin hydrocarbons eluting before and after an unknown solute A and \( t_R(N) \) and \( t_R(N + 1) \) = RT of paraffin hydrocarbons whose carbon numbers are \( N \) and \( N + 1 \), respectively.

The other available RI system is an ethyl ester index system. GC RIs are used alone or in conjunction with other analytical means for the identification of the unknown. The calculated RI of the unknown is compared with the literature database for the same column type. In GC analysis, the aroma quality of a volatile component combined with more than one RI value of different column types is considered as equivalent to identification by GC/MS. RIs together with GC/MS can have a much better performance for identification than GC/MS alone.

4.2 Mass Spectrometry

In flavor analysis, MS is one of the most powerful and effective methods in terms of identification. Together with GC, it provides both qualitative and quantitative information about the aroma from a complex food matrix. The GC column effluent is first ionized by electron bombardment to form a spectrum of ion fragments and then MS selectively allows fragments of a certain mass to charge ratio (\( m/z \)) to be analyzed under preset conditions. Quadrupole mass spectrometers provide a relatively lower resolution although they are more easily interfaced to various inlet systems. The other hand, by manipulating an electrical field with different geometries, an ion trap is created in an ion trap spectrometer. In this ion trap, fragments with specific \( m/z \) can be trapped, concentrated and stored prior to subsequent mass analysis. As a result, ion trap spectrometry is inherently more sensitive than other mass detection methods. Typically, full-scan spectra are possible even though the analytes are at picogram levels. The ion-storage ability of the ion trap has a useful application in advanced MS ion-preparation techniques (e.g. tandem MS), which greatly increases the analytical power of the instrument.

The mass spectrum obtained is a characteristic of the analyte. For identification, the mass data of each unknown are analyzed via computer matching with spectral databases of known compounds. The mass spectrum of an individual compound is unique. Nevertheless, a certain class of compounds do exhibit some common spectral features that are useful in identity differentiation. The features of a spectrum results from the fragmentation of a molecule, which characterizes itself from other molecules and from class to class. Flavor constituents ranging from aldehydes, ketones, alcohols and acids to heterocyclic compounds display their own characteristic patterns of fragmentation. More detailed information is available in Porter and Baldas, Ho and Carlin, Schwarzenbach and Gubler and Mottram.
The mass spectra derived from an ion trap mass spectrometer are slightly different from that obtained from a quadrupole mass spectrometer. The ion trap mass spectra usually have a profound \((M + 1)^+\) ion which make them more difficult to compare with most of the commercially available databases which were generated using quadrupole mass spectrometers.

### 4.3 Fourier Transform Infrared Spectroscopy

FTIR spectroscopy, based on the fact that there is a correlation between the wavenumbers at which a molecule absorbs infrared radiation and its structure, is a well-known analytical tool. Its power in elucidating a chemical structure by providing information about the functional groups within a molecule arises from the observation that functional groups tend to absorb infrared radiation in the same wavenumber range regardless of the structure adjacent to the functional groups. It is also able to provide quantitative information, such as the concentration of a molecule in a sample, on the basis of Beer’s law. However, FTIR spectroscopy by itself cannot necessarily be used to reveal the complete picture of an unknown. The development of infrared technology has advanced to combine it with different techniques such as GC, HPLC, ultraviolet/visible spectroscopy, MS and NMR spectroscopy, to enhance the overall analytical performance. The combination of GC and FTIR spectroscopy has proven to be very useful in analyzing complex mixtures quickly and accurately. GC/FTIR spectroscopy and GC/MS have been used to study flavors in products such as kiwi fruit, shiitake mushrooms and teas. Using GC, FTIR spectroscopy and MS together, Chang et al. identified a total of 74 compounds from bread crumbs and crust, of which 11 had bread-like odors. This research indicates that FTIR spectroscopy, especially when combined with other advanced analytical techniques, is complementary in identifying flavor compounds.

### 5 QUANTIFICATION OF VOLATILES

Quantification of volatiles in flavor analysis is routinely accomplished by using internal standards no matter which analytical technique is involved. In general, the chemical used as the internal standard should be stable under all conditions during analysis. It should have similar chemical and physical properties to the analyte and not react with the analyte to produce artifacts. The internal standard should be added to the sample matrix before any sample treatment so that it is processed simultaneously with the sample volatiles. For a liquid sample, the internal standard solution should be miscible with the sample matrix to ensure proper dispersion. In analyzing flavor components from solid material using a purge-and-trap or a thermal desorption technique, similar volatility of the internal standard to that of the analyte is desirable, and the introduction of an internal standard into the sample tube just before purging is advised to avoid preferential volatilization.

A combination of internal standard and appropriate response factors can be used for accurate volatile analysis and simultaneous determination of nonvolatiles. However, bias is difficult to avoid because it is impossible for an internal standard to have chemical and physical properties close to those of all chemical compounds in a mixture. In addition, the use of a traditional internal standard method is limited when quantifying trace levels of volatiles or compounds that are labile or polar. Overall, the traditional internal standard method is crude and often referred to as “semiquantitative”. For accurate quantification, the stable IDA can be used to target specific compounds. In this method, the isotope-labeled internal standard possesses the same chemical and physical properties as the analyte. Loss of analyte during the whole analysis period is also encountered by the standard. As a result, the accuracy is greatly enhanced. The advantage of IDA over other quantitative approaches has made it increasingly popular in both academia and industry. Several articles have provided detailed information about this method.

### 6 GAS CHROMATOGRAPHY/OLFACTOMETRY ANALYSIS

Although flavor analysis by GC/MS provides important information about the identity and chemical nature of volatile constituents obtained from food products, the identification of the multitude of volatiles reveals little direct insight into the actual flavor present in a food system. One reason is that many of the volatiles contribute little or nothing to the sensory character to the food product. In many cases the impact flavor compounds occur in small numbers and at low concentrations, and might not be detected by GC/MS. The discrepancy between the analytical contents and the sensory intensity of aroma chemicals led to the development of GCO, providing a link between complex chemical profiles and sensory perception. It is defined by Acree as the collection of techniques utilizing humans as detectors on gas chromatographs or gas chromatographs olfactometers to deliver pure doses of odorants to human subjects. The technique involves the sniffing of GC effluents to interpret sensory characteristics for chromatographically separated flavor compounds. The
concept behind the device is to split a portion of the effluent separated by a GC column to a “sniff port” while the majority of the effluent flows to a chemical detector for analysis. The effluents coming to the “sniff port” are sensed by a “sniffer”. In order to reduce the discomfort caused by sniffing hot carrier gases, Dravnieks and O’Donnell improved the original design by including humidifier air to cool the effluent and to reduce nasal dehydration. Years later, a higher resolution GCO system with additional features was described by Acree et al. who have pioneered GCO work in the last 10–15 years.

The objective of GCO is to identify flavor compounds and to elucidate their relative impact and the characteristic flavor of a food. This is accomplished by evaluating GCO data obtained via measuring two variables: perceived odor activity and chromatographic RT. RT by itself is rarely sufficient to identify an unknown chemical. It needs to be combined with other properties of the eluting chemical such as mass or Fourier transform spectra. One way of enhancing the usefulness of retention data from GCO is to convert RTs to RIs and compare the RIs with those in databases for flavor compounds. On the other hand, odor activity is a more complicated variable. It is characterized by odor quality identification, intensity assessment and potency quantification. Several terms such as “aroma value”, “unit flavor base”, “odor unit”, and “odor activity value” (OAV) have been used to describe the relationship of a compound’s concentration to its odor threshold in order to assess its odor significance. The potency of a flavor component relative to some other flavor components is a comparison of their dose levels at the same intensity response. It is a useful parameter to sort out the small number of contributing odorants from the very large number of odorless volatiles found in most natural products, fragrances and processed foods. The measurement of potency is most popularly carried out by two methods: AEDA and CharmAnalysis. Both methods are able to produce quantitative estimates of potency or relative potency for the various compounds that elute from a gas chromatograph. The process is typified by a series of extract dilutions usually at a ratio of 1:2 or 1:3. Each dilution is sniffed until no significant odor is detected and the presence or absence of odor is recorded for each dilution. In AEDA the number of dilutions necessary to eliminate the presence of an odor at a particular RT is used to estimate the potency of a specific odor. In CharmAnalysis, a chromatogram completed with peaks and quantified peak areas (called Charm values) is generated to quantify potency. The generation of a chromatogram involves a number of steps including a series of chromatographic runs. First, it is necessary to characterize RIs for the chromatographic system. The following GCO runs of actual sample extracts at a series of dilutions, with an internal standard added, are conducted in a randomized order, to prevent any possible bias. The olfactometer delivers the effluent to a “sniffer” who responds to the detection of an odor by depressing a button and holding it down till the odor changes in character or disappears and then selects a descriptive word for the odor detected. All the information thus obtained is incorporated into a software called CharmAnalysis. The RT intervals of each odor are plotted to produce a square peak at a fixed height. Charm chromatographs are constructed by summing the square peaks produced at a given RI from all the samples in a dilution series and then plotting peak areas at a specified RI versus dilution value. The added square areas are integrated into peak areas (charm values) by use of an algorithm partially for the purpose of reducing the disparity stemming from the chromatographic properties of an aroma compound. The peak areas, often referred to as Charm values, are believed to be proportional to the concentration of the odor-active compounds. Detailed information about how to conduct a CharmAnalysis is available in Acree et al.

AEDA shares a similarity with the CharmAnalysis technique. In AEDA, the GC effluent is split evenly between a flame ionization detector and a sniff port. GC injection is usually performed via the on-column technique that minimizes any chemistry associated with the injection process. RIs are also utilized to characterize the chromatography usually carried out on two different stationary phases. Both a polar and a nonpolar stationary phase are often used to chromatograph fractionated extracts in order to achieve maximum resolution of both polar and nonpolar constituents. Serial dilution usually proceeds in a continuous twofold pattern. The ratio of the concentration of the compound in the initial extract to its concentration in the most dilute extract in which the odor is detected by GCO is defined as flavor dilution (FD) factor which corresponds to the Charm value. The higher the FD factor of an odorant, the greater is its odor impact. FD values are plotted against the RI to obtain an FD chromatogram.

The primary difference between these two GCO techniques resides in the data obtained. The Charm value is based on peak area whereas the FD factor represents peak height. CharmAnalysis software was designed to request information that allows for peak reconstruction. AEDA is a simpler approach in that the GCO data acquisition is obtained solely based on the presence or absence of an odor determined by an individual.

As a powerful tool in analyzing aroma contributing components, GCO has found wide application in flavor analysis and is often used to detect trace amounts of
character impact compounds or off-odors in foods. It was used recently to investigate the characteristic lychee (Litchi chinesis Sonn.) fruit aroma and it was found that at least 10 compounds, including geraniol, guaiacol, cis-rose oxide, isobutyl acetate and furaneol, are significant odor contributors. It was concluded that the aroma of lychee is the result of interaction between compounds with floral, nutty, citrus and fruity aromas. Groesch\(^{[108]}\) has summarized the use of GCO and the character-impact odorants identified in olive oil, butter, Swiss cheese, meat, bread, beer and green tea and the study of off-flavors from several food items. A series of work using GCO to study the aromas of different types of raw and heated milk and fermented dairy products was reviewed by Friedrich and Acree.\(^{[109]}\) Other food items analyzed by GCO involving either CharmAnalysis or the AEDA technique include grape and grape juice,\(^{[110,111]}\) chocolate and cocoa\(^{[112]}\) and lobster meat.\(^{[113]}\) The list can be extended to numerous other products.\(^{[95,98]}\) Examples of the combined use of AEDA and headspace analysis include application to mushrooms.\(^{[114]}\)

One problem associated with AEDA and CharmAnalysis is their inconsistency with psychophysical views since both of these methods assume that the response to an odorous stimulus is linear, and that all compounds have identical response slopes with increasing concentration.\(^{[102,115]}\) Psychophysical views are based on the principles of Stevens’ law, which states that the response to a stimulus is an exponential rather than a linear event.\(^{[102]}\) A relatively new GCO method named Osme\(^{[116]}\) was developed and it conforms to this law. It is a quantitative bioassay method used to measure the response to odorants on a time–intensity scale.\(^{[115]}\) Unlike AEDA and CharmAnalysis, Osme is not based on an odor detection threshold.

The Osme method has been used to identify character-impact compounds in wine, hop oils, and beer\(^{[115]}\) and in apple flavor analysis.\(^{[102]}\) Piggott\(^{[117]}\) reported that Osme was more effective than odor-detection threshold techniques.\(^{[115]}\)

The aforementioned GCO techniques all have their own characteristics and are useful in determining the quality and potency of odorants in foods. However, limitations are still present. Information is obtained for individual compounds presented to the nose outside the food matrix,\(^{[102]}\) which influences the odor properties of these compounds. Bias can be introduced since findings by different GCO methods and their data analyses can be different in terms of which compounds are most important in a sample.\(^{[118]}\) Therefore, aroma reconstitution to confirm GCO results by sensory comparison with the original samples is necessary. This has been done for several food items including apple,\(^{[119]}\) cheddar cheese\(^{[120]}\) and strawberry juice.\(^{[121]}\)

The recent application of fluorescence spectroscopy to food analysis is reviewed and future trends in fluorometry are discussed. For food proteins, two techniques, i.e. intrinsic fluorometry and extrinsic fluorometry, are contrasted. Changes in the fluorescence intensity due to tryptophan and the anisotropy were measured in food proteins, including β-lactoglobulin, α-lactalbumin and lysozyme, to estimate changes in molecular structure during environmental alterations. Major applications of extrinsic fluorometry to food proteins are surface hydrophobicity measurements using hydrophobic probes. For this purpose, this approach is currently the most popular method in food protein chemistry probably because of the simplicity of the analytical technique. Advantages and disadvantages of various fluorescence probes and their applications were compared. Toxins are one of the most appropriate applications of sensitive fluorometry. Examples of the application shown here are mycotoxins and toxins of shellfish poisoning. For the former, capillary electrophoresis was introduced as a new tool. For the latter, the methods of derivatization are critical and therefore compared. For enumerating bacterial infection, bioluminescence using luciferase and direct epifluorescent filter technique (DEFT) are being used. Further, immunofluorescence is useful for specifically detecting pathogenic bacteria such as Salmonella, Listeria and enterotoxigenic Escherichia coli. Fluorescence caused by heating foods and fat oxidation was measured to assess their intensity. The thiobarbituric acid (TBA) reaction for measuring fat oxidation by colorimetry has been replaced frequently by fluorometry to improve the accuracy and specificity. Vitamins have been other popular analytes for fluorometry. Water-soluble and fat-soluble vitamins are discussed separately. High-performance liquid chromatography (HPLC) combined with fluorometric detectors is popular for the simultaneous analysis of multivitamins or multiforms of vitamins. Normal-phase HPLC of fat-soluble vitamins eliminated the need for solvent extraction and, in some cases, even the saponification process. As food additives, antibiotics (although they may be considered contaminants), aspartame and salicylates are discussed in this chapter. In amino acids analysis, reversed-phase high-performance liquid chromatography (RP-HPLC) with fluorometric detectors has replaced the traditional ion exchange–ninhydrin colorimetric detector systems because of simpler, quicker elution and higher sensitivity of detection. In enzyme chemistry, alkaline phosphatase (ALP) determinations of the adequacy of milk pasteurization and proteolytic enzyme activity are the most frequently reported methods in the recent literature. A fluorometric substrate is used for the former, which converts to a fluorescent form upon loss of a phosphate radical due to the action of ALP. For the latter, the same reagent as in amino acid analysis emits fluorescence upon reaction with an α-amino group yielded from proteins by proteolysis.

During the past one or two decades, fluorometry has in many cases replaced traditional colorimetry because of its higher sensitivity and selectivity. However, the modern automated, quicker separation technique achieved by RP-HPLC has, in some cases, allowed fluorometric detectors to be replaced by ultraviolet (UV) detectors. Although HPLC fluorometric detector systems will remain
as sensitive, versatile methods for analytes at very low concentrations, such as toxins and antibiotics, a substantial enhancement of sensitivity is achieved by using laser-induced fluorometry. This new trend is worth considering as a replacement for traditional radiolabeling techniques.

1 INTRODUCTION

Food analysis has exploited the characteristic advantages of fluorometry, i.e. high sensitivity and specificity. However, the advent of automated liquid chromatography (LC) with superior selectivity using more economical UV detectors is slowly replacing fluorometric analysis of components such as vitamin A in food, mainly because the amount of sample is not a crucial constraint in food analysis. Despite this, a combination of chromatography and fluorometry is still advantageous for detecting extremely low concentrations of contaminants such as toxins, pathogenic microbes, and antibiotics. Another important application of fluorometry in foods is the analysis of structure changes in proteins. Structure analysis is essential and, therefore, fluorometry is a very valuable tool for elucidating structure–function relationships of food proteins, such as the capacities of emulsifying, foaming, gelation, and film-formation.

The high selectivity of spectrofluorometry is due to use of two spectra, i.e. excitation and emission spectra, while the high sensitivity of the technique is a result of measuring radiation against absolute darkness, unlike UV–visible spectrometry, where each of two radiations is compared with its own deviation, i.e. the light reduced by the absorption caused by a sample against the bright reference blank without absorption. As a result, 100–1000 times higher sensitivity than that of spectrophotometry can be expected by using spectrofluorometry. However, spectrofluorometers with the two-spectra system are more expensive than UV–visible spectrophotometers with a single-spectrum system. Since the classic work of Udenfriend in 1969, many compounds in foods have been analyzed by fluorometry, namely proteins, peptides, amino acids, vitamins, carbohydrates, enzymes, steroids, some inorganic compounds, and toxins.

In 1989, the monograph entitled Fluorescence Analysis in Foods was published. This book covered mainly fluorescence microscopy and image analysis applied for analyzing mostly raw materials used in food processing, such as grains, meat, and fish, including the detection of contaminants such as fish bones. These techniques are also important for maintaining high quality of food products.

This chapter deals with two major categories, namely spectrophotofluorometry and its use in detectors in HPLC. Spectrofluorometry is a powerful instrumental analysis for measuring mainly structure changes in food proteins, whereas HPLC with fluorometric detection is currently utilized in analyzing toxins, pathogenic microbes, heating effects, fat oxidation, vitamins, additives, amino acids, and enzyme activity in foods.

Use of laser-induced fluorescence spectroscopy for analysis of ochratoxin A (section 3.1) and vitamin (section 7) exemplifies recent advancement in laser-induced fluorescence spectroscopy with a detectability comparable to that of radiolabeling methods. Considering the dramatic progress made in modern analytical techniques, only those topics which have appeared in recent literature have been reviewed in this chapter rather than covering all possible areas of application in fluorescent analysis of foods.

2 PROTEIN STRUCTURE

The recent most thorough coverage of fluorescence spectroscopy in proteins and enzymes was made in the book edited by Brand and Johnson. Readers are also recommended to refer to the article Fluorescence Spectroscopy in Peptide and Protein Analysis in this encyclopedia. However, in this article, the topics center on the methods that are popular in the analysis of food proteins. They involve fluorescence intensity, polarization, and energy transfer based on intrinsic as well as extrinsic fluorescences, and surface hydrophobicity using extrinsic probes.

Absorption of light by a molecule raises the energy level from the ground state to an excited state. The excited molecule returns to the ground state by emitting light or by losing energy in the form of heat (vibrational relaxation) or chemical change. The ratio of the energy emitted to the total energy absorbed is the quantum yield. The characteristic time delay between absorption and emission of a photon, usually 1–10 ns, is the fluorescence lifetime. Fluorescence can be quenched by interactions with other molecules or its environment. Energy transfer measures the transfer efficiency within the distances from 0.5 to 10 nm between energy donor and acceptor molecules. Fluorescence of a ligand, e.g. a dansyl group, increases upon binding to protein. This effect is caused either by a change in the polarity of the microenvironment, or by an energy transfer between tryptophan residue(s) in the protein and an acceptor in the ligand. When polarized light is used for excitation, the plane of polarized light can be altered by a fluorophore. The extent of depolarization is expressed as polarization, \( p = (I_v - I_h)/(I_v + I_h) \), or anisotropy, \( r = (I_v - I_h)/(I_v + 2I_h) \), where \( I_v \) and \( I_h \) are vertical and horizontal

fluorescence intensities respectively. The fluorescence anisotropy is a measure of the inequality in molecular movement in solution.

For food proteins, an excellent review was published by Strasburg and Ludescher, who have provided a comprehensive explanation of the principles of the different fluorescent technologies that have been utilized in food analysis.

2.1 Intrinsic Fluorometry

Tryptophan is the most widely used intrinsic probe in proteins. The emission peak is at about 350 nm in water but shifts to about 315 nm in nonpolar media, such as within hydrophobic regions in the interior of the folded proteins. Protonated amino and carbonyl groups, as well as amide bonds, readily quench tryptophan fluorescence, with a quantum yield typically in the range 0.1–0.5. Changes in fluorescence intensity due to variation in quencher proximity provide a sensitive indicator of alterations in protein conformation, such as those resulting from protein–ligand binding, protein–protein associations or protein denaturation. Changes in intrinsic anisotropy can be utilized to monitor shape variations derived from protein unfolding, mass changes resulting from aggregation, or conformational transitions associated with a change in a particular protein domain. When proteins do not contain tryptophan, tyrosine residue(s) can be used instead as in the case of tryptophan residues.

The two tryptophan residues, i.e. Trp19 and Trp61, in β-lactoglobulin are inaccessible to water by being buried in hydrophobic environments in the protein interior. Changes in the fluorescence intensity and emission wavelength have been used to monitor the denaturation. The protein undergoes reversible conformational changes at 50 °C, thereby affecting one Trp residue, while a second irreversible change occurs at 70 °C affecting another residue. Shifts in pH affected the anisotropy, and the relaxation times for rotational motion were in good agreement with those expected for the monomer, dimer, and octamer. The supramolecular associating properties of β-lactoglobulin were investigated by measuring concentration dependence of the accessibility of backbone exchangeable amide proton by H/D exchange in nuclear magnetic resonance (NMR) and by their intrinsic fluorescence features. The weak forces involved in this association were different from those stabilizing the native dimer.

Binding of retinol to β-lactoglobulin has been measured using retinol fluorescence through energy transfer from the intrinsic Trp. Similarly, the binding with phosphatidylcholine has been reported. Tryptophan fluorescence of chicken lysozyme and α-lactalbumin in native and modified forms and fragments of these proteins has been investigated using the iodide ion as a quencher.

Exposure of Trp residues in both proteins has been determined. Effects of heating through a Maillard reaction on β-lactoglobulin–lactose mixtures have been investigated by monitoring the formation of fluorosine and the decrease in the Trp fluorescence quantum yield.

2.2 Extrinsic Fluorometry

Rhodamine maleimide is being used to label the calcium-binding protein calmodulin to investigate the binding with channel protein using fluorescence polarization. This interaction is likely to play an important role in the mechanism of pale, soft exudative pork.

Another covalent extrinsic probe used is Iaedans [5-((2-iodacetyl)amino)ethyl]amino)naphthalene-1-sulfonic acid], which binds with sulfhydryl groups in muscle proteins. By observing the variations in fluorescence intensity, conformational transitions of the proteins due to environmental changes can be assessed.

Most other studies have been conducted by using noncovalently binding extrinsic probes to investigate the relationships with protein functionality. Another covalent extrinsic probe used is Iaeudans [5-((2-iodacetyl)amino)ethyl]amino)naphthalene-1-sulfonic acid], which binds with sulfhydryl groups in muscle proteins.

Another group of anionic fluorescence probes is the popular hydrophobic probe for the determination of surface hydrophobicity of proteins. Occasionally, its dimeric form, bis-ANS, which has a greater quantum yield in nonpolar environments as a result of binding with proteins stronger than the monomer ANS, is used for the same purposes. These effects permit observation of depolarization by energy transfer among the bound fluorophores, which can be used to estimate the distribution of the ligands among the protein molecules.

Cardamone and Puri stated that ANS binding and the resultant Ks measured by a Scatchard or Kloz plot and, to a lesser extent, quantum yield may be used as a measure of the relative surface hydrophobicity of proteins. Titration of protein solutions containing increasing concentrations of the fluorescent probe can provide information on both the number and the affinity of binding sites. This may be useful in determining whether a high intensity of fluorescence results from the presence of many binding sites of only moderate hydrophobic character, or from the existence of a high-affinity site with considerable hydrophobic character.

The application of fluorescence probes to investigate the proximity of the probe binding site(s) and aromatic groups has also been assessed by measuring the efficiency of energy transfer in casein micelles. Transfer of excitation energy from aromatic chromophores to bound probe at an adjacent hydrophobic site causes quenching of the intrinsic fluorescence in the aromatic side chain. This transfer efficiency has also been measured as an index of surface hydrophobicity.

Another group of anionic fluorescence probes is the fatty acid analog type, including cis-parinaric acid (CPA)
and trans-parinaric acid, which has been used as a probe for proteins and biological membranes.\(^{(18)}\) The parinaric acids are among the few known nonaromatic fluorophores. Their similarity to native fatty acids, nonfluorescence in water, and good Stokes’ shift characteristics are among the advantages of their use to probe for hydrophobic regions that may be important in protein–lipid interactions in food systems. Good correlations were obtained between the relative hydrophobicity values of proteins determined by CPA fluorescence and the properties related to protein–lipid interactions, such as interfacial tension and emulsifying activity.\(^{(19)}\) This is an aliphatic hydrophobicity that can be differentiated from the aromatic hydrophobicity by using aromatic fluorophores, such as ANS.\(^{(20)}\) The latter may be useful in investigating protein–protein interactions, such as those with retinol and aromatic flavor compounds. ANS and CPA were both used for the elucidation of heat-induced gelation of myosin.\(^{(21)}\)

A limitation in using anionic probes such as ANS and CPA to determine protein hydrophobicity includes a possibility that electrostatic as well as hydrophobic interactions may contribute to the interaction with probes.\(^{(22)}\) The use of neutral, e.g. prodan (6-propionyl-2-dimethylaminonaphthalene),\(^{(23)}\) or uncharged probes, e.g. 1,6-diphenyl-1,3,5-hexatriene (DPH),\(^{(24)}\) may circumvent this problem. However, the nonpolar nature of DPH restricts its solubility in aqueous systems and thus limits its use as a probe for protein solutions, although it is not the absolute deterrent.\(^{(24)}\)

Binding with hydrophobic probes was utilized to investigate the effects of heating milk proteins\(^{(25)}\) and soy proteins.\(^{(26)}\) Not only ANS binding, but also intrinsic tryptophan fluorescence, was used for the same purpose in \(\alpha\)-lactalbumin,\(^{(27)}\) \(\beta\)-lactoglobulin,\(^{(28)}\) and gluten.\(^{(29)}\) The effects of heating, the addition of dissociating agents, and S–S cleavage on the emulsifying properties of soy proteins were studied by using CPA hydrophobicity.\(^{(30)}\) Similarly, the effects of pH and NaCl on the emulsifying and foaming properties of cowpea globulin have been investigated.\(^{(31)}\) The importance of surface hydrophobicity in rennet coagulation of milk proteins was discovered by using fluorometry.\(^{(17,32)}\)

### 3 TOXINS

Fluorometry is one of the most valuable instrumental analytical techniques for determining causes of food poisoning by analyzing toxins. More powerful tools such as NMR, gas chromatography (GC)/mass spectrometry (MS), supercritical fluid chromatography (SFC)/MS, atmospheric pressure ionization (API)/LC/MS, MS/MS, GC/Fourier transform infrared (FTIR), and SFC/FTIR can also be used for measuring and/or identifying toxins.\(^{(33)}\) However, HPLC with fluorometric detection is still the analytical tool of choice for many researchers, probably because of lower installation costs and the versatility of the instrument for multianalytical purposes.

#### 3.1 Mycotoxins

Aflatoxins are mycotoxins (fungal toxins) are named from “A. fla”’vus derived ‘‘toxin”. They are toxic secondary metabolites produced by fungi, primarily of the genus Aspergillus, e.g. Asp. flavus and Asp. parasiticus. These toxins are found as natural contaminants in foods and feeds, including peanuts, corn, and other grains. Aflatoxins are converted metabolically in the bodies of humans and domestic animals to potent liver carcinogens.\(^{(34)}\) Because of their strong carcinogenic nature, aflatoxins are regulated at much lower levels than any other mycotoxins, usually at <20 ppb. Cole and Cox\(^{(35)}\) reported 16 aflatoxins. However, only aflatoxins B\(_1\) and B\(_2\), which exhibit a blue fluorescence; G\(_1\) and G\(_2\), which show a yellow–green fluorescence; and M\(_1\), which is found in milk as a metabolite produced in animals fed aflatoxin B\(_1\), are routinely monitored in foods and feeds. The fungi can produce aflatoxins in their natural habitat under stress conditions or in storage under moist conditions (85%) at 25–40\(^\circ\)C.

Aflatoxin B\(_1\) is the most prevalent, toxic, and carcinogenic of all the aflatoxins. Because of the potential health hazards for humans, analysis of aflatoxins in various foods is important from the food safety aspects. Efforts to minimize aflatoxin contamination in susceptible commodities are the subject of many food research projects.

Thin-layer chromatography (TLC) has long been the most popular method for analysis of aflatoxins. However, owing to higher accuracy in quantification, HPLC, especially RPHPLC, has replaced TLC. Native fluorescence at \(\lambda_{ex} = 360\) nm for all four aflatoxins (\(\lambda_{em} = 440\) nm for aflatoxins B\(_1\) and B\(_2\), and 470 nm for aflatoxins G\(_1\) and G\(_2\)) has been used for detection of aflatoxins after separation using HPLC. A UV detector at 365 nm is also utilized to monitor the effluents from the chromatography column, but a fluorescence detector is required to improve the accuracy of detecting aflatoxins B\(_2\) and G\(_2\).

The weak native fluorescence of aflatoxins may be intensified by using, for instance, trifluoroacetic acid. Acid-catalyzed precolumn derivatization converts aflatoxins B\(_1\) and G\(_1\) to the corresponding saturated hydroxy derivatives B\(_{2A}\) and G\(_{2A}\). Another method of enhancing fluorescence is the postcolumn derivatization of aflatoxin B\(_1\), which is achieved by the action of iodine or bromine, thereby increasing the fluorescence 25-fold.
Kok et al.\textsuperscript{(36)} described the optimum operating conditions of the electrochemical KOBRA\textsuperscript{TM} cell to generate bromine for the same purpose and applied this technique to the determination of aflatoxins in cattle feed. A reversed-phase (RP) C\textsubscript{18} column was used, with a mobile phase of water–methanol–bromide including nitric acid. The aflatoxins were monitored using a fluorescence detector at $\lambda_{ex} = 360 \text{ nm}$ and $\lambda_{em} > 420 \text{ nm}$. The detection limits were reported to be 0.04 ng for aflatoxins B\textsubscript{1} and G\textsubscript{1}, and 0.02 ng for B\textsubscript{2} and G\textsubscript{2}. Aflatoxin M\textsubscript{1} in goat dairy products was analyzed using HPLC with a fluorescence detector after the sample had been cleaned by using an immunoaffinity column.\textsuperscript{(37)} The mycotoxin was detected in about 30\% of samples from dairy farms at levels ranging from 4 to 37 ng l\textsuperscript{−1} for milk and 19–160 ng kg\textsuperscript{−1} in cheeses.

Capillary electrophoresis with a laser-induced fluorescence detector was used to determine ochratoxin A in roasted coffee, corn, and sorghum.\textsuperscript{(38)} This fungal toxin is one mycotoxin that is routinely monitored due to its high toxicity and widespread occurrence in foods and feeds. The extraction and isolation procedures are carried out using a silica column and an immunoaffinity cleanup column analogous to other chromatographic methods for aflatoxins.

Capillary electrophoresis has also been used in corn samples to analyze fumonisin B\textsubscript{1}, a mycotoxin produced by species of \textit{Fusarium}. As this toxin did not have a UV chromophore, it was fluorescein-labeled.\textsuperscript{(39)} Zearalenone is another toxin produced by \textit{Fusarium} molds, which grow on corn that is immature or has a high moisture content at harvest. After separating by RPHPLC on a C\textsubscript{18} column, it was determined fluorometrically.\textsuperscript{(40)} Despite the higher costs of instrumentation, HPLC/MS is more advantageous due to greater sensitivity and selectivity, without the need for derivatization as in fluorometry.

### 3.2 Toxins of Paralytic Shellfish Poisoning and Diarrhetic Shellfish Poisoning

Paralytic shellfish poisoning (PSP) toxins include saxitoxin, neosaxitoxin and gonyautoxins, which show neither UV absorption nor fluorescence. Oxidation under alkaline conditions, e.g. with NaOH–H\textsubscript{2}O\textsubscript{2}, converts most of PSP toxins to fluorescent forms, which can be used in postcolumn derivatization after eluting from RPHPLC columns. The tolerance levels of PSP are 40–80 µg per 100 g, and HPLC can detect individual PSP toxins below the 1 µg per 100 g level.

Diarrhetic shellfish poisoning (DSP) toxins, including okadaic acid and its derivatives, are named dinophysistoxins (DTX), pectenotoxins (PTX), and yessotoxin (YTX). To make fluorometric detection feasible, two derivatizations have been proposed using the reactions with 9-anthyldiazomethane (ADAM) and 4-bromomethyl-7-methoxycoumarin (Br-Mme). Since ADAM derivatives require an additional cleanup process and are unstable, the Br-Mme derivatization has been more popular, thus being extensively used. A convenient one-vial procedure using Br-Mme for esterification of okadaic acid and DTX-1 to give a fluorescent coumarin ester at $\lambda_{ex} = 325 \text{ nm}$ and $\lambda_{em} = 390 \text{ nm}$ has been developed.\textsuperscript{(41)} For HPLC of the Br-Mme derivatives, the use of a C\textsubscript{18} RP column and isocratic elution with acetonitrile–water (70:30) has been suggested. Contamination levels of 0.03–2.5 mg DSP kg\textsuperscript{−1} have been reported.\textsuperscript{(42)} Proposed tolerance levels are 20–60 µg per 100 g and the application of HPLC to the determination of the acidic components of DSP complex allows the detection of 10 µg of okadaic acid and/or DTX-1 in 100 g of shellfish meat.

## 4 BACTERIA

According to the literature, fluorometry to detect bacteria-infected foods either relies on their bioluminescence or utilizes immunofluorescence assays.

### 4.1 Bioluminescence

Bioluminescence is used in food analysis to detect bacterial adenosine triphosphate (ATP). In the presence of ATP and magnesium ions, luciferin is oxidized to oxyluciferin, which releases a photon by the action of the enzyme luciferase. The number of photons of light emitted is proportional to the amount of ATP initially present in the sample.\textsuperscript{(43)} Luciferase reactions are rapid and the emitted light can be measured by a luminometer and the results converted to the number of bacterial cells per ml of sample. A number of automated luminometer systems are commercially available for assessing bacterial ATP,\textsuperscript{(44)} and sensitivities range from 10\textsuperscript{3} to 10\textsuperscript{4} cells ml\textsuperscript{−1}.

Another fluorescence system to enumerate viable bacteria is the DEFT.\textsuperscript{(45)} The monomeric fluorochrome acridine orange binds with double-stranded DNA, thereby emitting a green fluorescence. However, when cells are actively dividing, the fluorescence changes to orange as the binding is to single-stranded RNAs produced as a result of bacterial division. In the DEFT procedure, bacterial cells in food samples are pretreated with trypsin, filtered through a polycarbonate membrane, stained with acridine orange and then the number of orange cells on the filter is counted under a fluorescence microscope.

### 4.2 Immunofluorescent Assays

Antibodies can be labeled with fluorescein isothiocyanate (FITC) to identify bacteria. \textit{Salmonella} serotypes in foods
were identified by this method, which was also applied for the detection of *Listeria monocytogenes* in food samples. A solid-phase fluorescent capillary immunoassay was developed to detect *Escherichia coli* O157:H7 in foods. A soft glass capillary tube served as the solid support, to which heat-killed *E. coli* O157:H7 were adsorbed. Polyclonal anti-*E. coli* O157:H7 antibody conjugated with biotin was used, and the bound antigen–antibody complex was detected using avidin labeled with Cy5, a fluorescent cyanine dye. Any *E. coli* O157:H7 in the sample would compete with the formation of this complex, thereby reducing fluorescence. This assay was tested for sensitivity with spiked ground beef and apple cider samples. The minimum detectable number of cells present in the initial inoculum was approximately 1 colony forming units (CFU) per 10 g of ground beef when the samples were enriched by incubating for 7 h at 37°C. In the case of apple cider, *E. coli* cells were collected using immunomagnetic beads, and then the fluorescent immunoassay was performed as in the case of beef samples.

5 HEATING

Protein-bound Maillard compounds were hydrolyzed with proteinase or acid and separated by ion-exchange chromatography. Effluents were detected directly with a fluorescence detector. Fluorescent peptides resulting from casein/lactose interaction in milk by heating were determined by RPHPLC. Heterocyclic aromatic amines are mutagenic compounds that are formed during heating of meat and fish. These substances are produced by the reaction of creatine with amino acids and carbohydrates. One of those compounds, i.e. 2-amino-1-methyl-6-phenylimidazo[4,5-b]pyridine (PhIP) is fluorescent and can be separated by HPLC.

Fluorescence was the technique that provided the best models for anisidine value, oligomers, iodine value, and vitamin E in deteriorated oil after repeated frying cycles. Algal phycobiliprotein, fluorescent phycoerythrin, can be applied as the detecting component of a time–temperature integrator for monitoring thermal processing of foods.

6 FAT OXIDATION

The methods to measure lipid oxidation are divided into two categories: primary changes and secondary changes. The ideal method to measure lipid oxidation is the direct measurement of initial products of oxidation, i.e. hydroperoxides. Recently, much research has been conducted into the association between oxidation and clinical disease. Therefore, research has been focused on the determination of hydroperoxides rather than secondary changes. The analytical procedure to be used for this purpose should be sensitive, precise, and specific.

Lipid oxidation is one of the major causes of quality deterioration in meats and fish. Gray and Monahan reviewed the measurement of lipid oxidation in meats and fish. Several methods have reported the extent of lipid oxidation in freeze-dried meat and fish using fluorescence techniques. Recently, Hasegawa et al. reported a procedure for evaluating oxidative deterioration in dried fish by measuring protein-bound fluorescence.

Detection of lipid hydroperoxides by HPLC has been reviewed by Yang. Two postcolumn detection methods were compared, i.e. the chemiluminescence of luminol and the spectrophotometric determination of I3-. Miyazawa et al. measured lipid hydroperoxides in meats and fish using the fluorometric peroxygenase assay. Hydroperoxide is reduced to alcohol in equimolar concentration in a reaction catalyzed by peroxygenase during hydroxylation of the substrate, 1-methylindole. The method can determine total lipid hydroperoxides in a sample without extraction.

The flow injection analysis (FIA) of Akasaka et al. was highly sensitive. After sample injection, lipid hydroxides were reacted with diphenyl-pyrenylphosphine (DPPP) in a stainless steel coil, and the fluorescence intensity of hydroperoxide showed good linearity between 0.4 and 79 pmol with a detection limit of 0.2 pmol.

The primary products from lipid oxidation decompose to form secondary products. Among these secondary products, malondialdehyde (MDA) has been used as an index of oxidation in foods. The 2-thiobarbituric acid (TBA) method is most popular for the measurement of MDA, despite a criticism for lack of specificity and sensitivity. Recently, chromatographic methods (GC or HPLC) have provided more specific and sensitive determination of MDA than the TBA method. Samples of homogenized butter, margarine, oil, fish, and meat tissue were treated with 5% trichloroacetic acid to remove protein. The supernatant was incubated in 0.28% TBA for 30 min. The MDA/TBA adduct thus produced was detected by measuring fluorescence (λex = 515 nm, λem = 543 nm) after eluting from the RPHPLC column.

Even though the chromatographic method is specific and sensitive, the TBA method is still frequently preferred over chromatographic methods because of its simplicity. The TBA method was reviewed by Hoyland and Taylor. Raharjo et al. reported an improved...
TBA method for measuring lipid peroxidation in beef. Substances interfering with the MDA/TBA reaction were removed by using a Sep-Pak C18 cartridge. The method was adequately fast, specific, and sensitive.

Raharjo and Sofos\(^\text{58}\) reviewed procedures for the analysis of MDA in muscle tissue. Several modified TBA procedures were discussed in their review article. Jo and Ahn\(^\text{62}\) developed a sensitive and reliable fluorometric analysis of TBA reactive substances in turkey meat. This method is useful for samples with low-level lipid oxidation.

### 7 VITAMINS

Vitamin determination in food analysis is very important in efforts to minimize nutrient losses before and after processing,\(^\text{63}\) to fortify foods with vitamins,\(^\text{64}\) or to use vitamins as food additives such as antioxidants.\(^\text{65}\)

Microbiological, biological, and enzymatic assays have been applied to determine vitamin concentration.\(^\text{66}\) In recent years, HPLC in the RPHPLC mode or normal-phase mode has been widely applied for determination of both fat-soluble and water-soluble vitamins.\(^\text{60}\) HPLC provides a wide range of separation and detection methods. Fluorescence detection provides improved sensitivity and selectivity compared with UV detection as already discussed. Postcolumn derivatization methods have frequently been employed in the HPLC determination of vitamins in foods.

Rahn\(^\text{67}\) submitted excellent summary tables for fluorometric analysis of vitamins in foods. According to Rahn, there are two types of fluorescence that can be used for analysis, i.e. natural fluorescence of vitamins A, B₂, folic acid, and E, and the fluorescence of vitamins C and K₃ derived from condensation with o-phenylenediamine (OPD). His table includes vitamins A, B₁, B₂, B₆ (folic acid), B₉ (nicotinamide), B₁₂, B₁₃, C, D, E, K₁ (phytoquinone), and K₃ (menadione). Another table summarizes the results of laser-induced molecular fluorescence.\(^\text{68}\) Several vitamins and amino acids could be detected at the parts per trillion level, indicating a tremendous improvement of several orders of magnitude over the detection limit achieved by conventional light sources.

#### 7.1 Water-soluble Vitamins

Water-soluble vitamins (B₁, B₂, and C) have been separated by RPHPLC and measured by using fluorescence detection.\(^\text{60}\) Vitamin B₁ consists of a substituted pyrimidine linked by a methylene group to a substituted thiazole.\(^\text{63}\) In analysis, thiamine is usually treated with a strong oxidizing agent to form fluorescent thiochrome. Vitamin B₂ occurs naturally in three principal forms, i.e. riboflavin (RF), flavin mononucleotide (FMN), and flavin adenine dinucleotide (FAD).\(^\text{69}\) FMN and FAD are converted to RF, and total riboflavin (TRF) is assayed fluorometrically. However, this method is tedious, and time-consuming, and needs laborious sample preparation.\(^\text{69}\)

Sims and Shoemaker\(^\text{70}\) reported simultaneous determination of thiamine and RF using HPLC with fluorescence detection (\(\lambda_{ex} = 370\ nm, \lambda_{em} = 435\ nm\) for thiochrome, \(\lambda_{ex} = 370\ nm, \lambda_{em} = 520\ nm\) for RF). Fernando and Murphy\(^\text{71}\) also measured thiamine and RF in soybeans and tofu using wavelengths \(\lambda_{ex} = 364\ nm, \lambda_{em} = 436\ nm\) for thiochrome, and \(\lambda_{ex} = 436\ nm, \lambda_{em} = 535\ nm\) for RF. Russell and Vanderslice\(^\text{72}\) studied non-degradable extraction and simultaneous quantification of RF, FMN, and FAD by HPLC. The method was successfully applied to a variety of foods, including raw and cooked meats, dairy products, eggs, and cereal products. The results of these HPLC analyses generally agreed with the published values for TRF. Russell and Vanderslice\(^\text{69}\) modified the standard fluorometric determination of RF (\(\lambda_{ex} = 440\ nm, \lambda_{em} = 565\ nm\)) to permit more convenient quantification by FIA.

An HPLC method with fluorometric detection (\(\lambda_{ex} = 333\ nm, \lambda_{em} = 375\ nm\)) was applied for analysis of vitamin B₆ in foods and feeds.\(^\text{73}\) High recovery and precision were reported in comparison with a microbiological assay using Saccharomyces uvarum. Simultaneous determination has been reported for the measurement of thiamine, RF, and pyridoxine in medical foods\(^\text{74}\) and in infant formula.\(^\text{75}\) A fluorometric detector was programmed to detect B₂ and B₆ simultaneously, and then thiochrome. RPHPLC was used for thiamine, RF, and pyridoxine in medical foods.\(^\text{74}\) Vitamin B₁₂ was postcolumn derivatized to thiochrome. Vitamin B₁₂ was labeled with a fluorescent reagent [6,7-dimethoxy-1-methyl-2(1H)-quinoxaline-3-propionylcarboxylic acid hydrazide] and determined over a range of 0.2–10 \(\mu\)g L\(^{-1}\) of fluid samples of foods.\(^\text{76}\)

The reduced form and the oxidized form of vitamin C are referred to as ascorbic acid and dehydroascorbic acid, respectively. The total vitamin C activity is the sum of both forms.\(^\text{77}\) Precolumn or postcolumn derivatization can enhance the sensitivity of dehydroascorbic acid measurements by fluorescence detection. Ascorbic acid has been measured based on the rapid oxidation of ascorbic acid, which then reacts with OPD to form a fluorescent quinoxaline. Total vitamin C was measured by HPLC with precolumn derivatization with OPD.\(^\text{77}\) This method could analyze various foods, including complex matrices of canned corn, potatoes, green beans, potato chips, and cereals, by avoiding the effect of interference.
matrix. Simultaneous determination of ascorbic, dehydroascorbic, isoascorbic, and dehydroisoascorbic acids in meat-based food products was reported using RP-HPLC with a postcolumn fluorescence detector.\(^{(78)}\) Similarly, HPLC/fluorescence methods were developed for vitamin K\(_1\)\(^{(79)}\) and folate in foods.\(^{(80)}\)

### 7.2 Fat-soluble Vitamins

Numerous HPLC procedures have been reported for fat-soluble vitamins. They are extracted with nonpolar solvents after saponification and separated by either normal or RP-HPLC.\(^{(66)}\) The procedures have been simplified by eliminating extensive sample preparation and interference.

A simple and rapid method for the determination of retinol in whole milk has been described.\(^{(81)}\) It involves sample preparation, saponification, and extraction in the same tube, thereby avoiding the risky and time-consuming evaporation of solvent. The retinol is then separated by HPLC with fluorescence detection (\(\lambda_{ex} = 344\) nm, \(\lambda_{em} = 472\) nm). The method is rapid, sensitive, and precise for milk samples of small sizes.

Vitamin E is found in nature in the form of a number of tocopherols and tocotrienols. Analytical procedures involve extraction, saponification, and chromatography of the nonsaponifiable matter by TLC or GC.\(^{(66)}\) LC with fluorescence detection has been widely utilized for the determination of vitamin E activity in various foods. Ang et al.\(^{(82)}\) used RP-HPLC with fluorescence detection (\(\lambda_{ex} = 275\) and 280 nm, \(\lambda_{em} = 330\) nm) for measurement of the level of different forms of tocopherol in chicken breast and leg muscles and to assess the effect of cooking on the stability of these tocopherols. Razagui et al.\(^{(83)}\) reported a spectrofluorometric method to measure \(\alpha\)-tocopherol for detecting nutritional supplement products (\(\lambda_{ex} = 298\) nm, \(\lambda_{em} = 330\) nm). The procedure was reported to be very accurate and without interference.

An intercomparison of the methods for vitamin determination was organized in 1993 involving 18 European laboratories.\(^{(84,85)}\) HPLC with a fluorescence (sometimes UV) detector was used to analyze retinol, \(\beta\)-carotene and \(\alpha\)-tocopherol in milk powder, pork muscle, and haricot vert beans. Relative standard deviations of reproducibility (RSDR) were 10–16% except for \(\beta\)-carotene in haricot vert beans (52%). RSDR of vitamins B\(_1\), B\(_2\), B\(_6\) and C were 9–18%, except for vitamin B\(_2\) (28–74%) and B\(_6\) (18–51%).

Normal-phase HPLC with a silica column was used to analyze vitamins A and E and \(\beta\)-carotene in dairy foods\(^{(86)}\) and vitamin E in beef muscle.\(^{(87)}\) Lipids extracted with organic solvents were directly applied to the column without saponification for the former, while saponified extracts were applied for the latter.

### 8 ADDITIVES

Food additives are used to improve flavor, color, texture, and shelf life. Among the food additives, fluorometric analysis of antibiotics, aspartame and salicylates has appeared in recent literature. Antibiotics might not belong to this category in a strict sense, but as they have been inadvertently contained in foods, it was decided to discuss them here.

#### 8.1 Antibiotics

Antibiotics have been used mainly in dairy herds and fish farming. Antibiotics can cause allergic reactions in humans, therefore it is important to detect them in order to prevent health hazards from contaminated foods.

Rapid screening tests using commercial test kits are available for the detection of antibiotics.\(^{(88)}\) They are microbial inhibition assays (Delvotest P, Delvotest SP, and AIL’96) and enzyme receptor tests (SNAP, LacTek, Charm II, Delvo-X-Press BLII, BetaScreen 4P, Paralux, EZ-Screen and Ridscreen). The limitation of these methods is sometimes their lack of specificity. Among these test kits, BetaScreen 4P and Paralux use fluorescence as the detection mechanism. BetaScreen adopts an enzyme-linked immunosorbent assay (ELISA)-based test using fluorescence and ALP.\(^{(88,89)}\) A novel qualitative enzyme immunoassay based on fluorescence detection was used to determine \(\beta\)-lactam antibiotics in milk.\(^{(90)}\) The assay is specific to six \(\beta\)-lactams. Paralux is based on a solid-phase fluorescence immunoassay (SPFIA) and can detect up to six \(\beta\)-lactam antibiotics.\(^{(88)}\)

LC is one of the most reliable techniques for detecting traces of antibiotics. Payne et al.\(^{(90)}\) determined epirinometin marker residue in edible bovine tissue using HPLC with fluorescence. It is rapid, sensitive, and selective. Sarafloxacin residues in chicken eggs were analyzed by on-line microdialysis and HPLC with programmable fluorescence detection.\(^{(91)}\) Ang and Luo\(^{(92)}\) described the precolumn derivatization procedure using HPLC with fluorescence detection for rapid determination of ampicillin in raw and pasteurized milk. Amoxicillin and ampicillin in milk were determined simultaneously by HPLC after derivatization.\(^{(93)}\) Four fluoroquinolones in milk were measured by HPLC with fluorescence detection.\(^{(94)}\) The limit of detection was 1.8 µg penicillin G kg\(^{-1}\). Similarly, spectinomycin and penicillin G were determined by a rapid detection assay.\(^{(95)}\) Also, tetracycline and oxytetracycline were determined in meat and fish in a similar fashion.\(^{(96)}\) Oxytetracycline was detected by this method at the level of 5 ng g\(^{-1}\) in meat and fish, and 1 ng g\(^{-1}\) in eggs. The coefficient of determination (relative standard
deviations) at 50 ng g\(^{-1}\) and 200 ng g\(^{-1}\) ranged from 1.6% to 3.1%.

Sulfonamides (sulfadiazine, sulfathiazole, sulfethazine, sulfamonomethoxine, sulfamethoxazole, sulfadimethoxine) were analyzed using LC with fluorescence.\(^{(97)}\) The method was rapid and simple. Laloux et al.\(^{(98)}\) also determined sulfonamides in milk after fluoresceamine derivatization. Gerhardt et al.\(^{(99)}\) reported a procedure for analyzing streptomycin and dihydrostreptomycin in milk. These antibiotics were detected by fluorescence following postcolumn derivatization with 1,2-naphthoquinone 4-sulfonic acid.

Aquaculture has magnified concern about drugs used in fish farming. LC with fluorescence has been used for the detection of different antibiotics, e.g. quinolones and sulfonamide. Pfenning et al.\(^{(100)}\) determined residues of flumequine and nalidixic, oxolinic, and piromidic acids in salmon and shrimp using LC with simultaneous UV and fluorescence detection. Amoxicillin in catfish and in salmon and shrimp using LC with UV detection and fluorescence detection was also used to determine sulfonamides in channel catfish muscle tissue.\(^{(101)}\) Sulfonamides in salmon tissue were measured by LC with postcolumn derivatization and fluorescence detection.\(^{(102)}\)

### 8.2 Aspartame

Aspartame, \(N\)-L-\(L\)-aspartyl-L-phenylalanine 1-methyl ester, is a low-calorie sweetener which is 200 times sweeter than sugar. Aspartame is used to sweeten or enhance fruit flavor in a variety of foods and beverages. Aspartame is composed of two amino acids, aspartic acid and the methyl ester of phenylalanine. Upon digestion, aspartame breaks down into aspartic acid, phenylalanine and methanol.

Speedy and simple analysis of aspartame is required for quality control purposes. Many analytical procedures have been employed to determine the concentration of aspartame and its decomposition products, which have been formed during manufacturing and storage of food products. One of these analytical methods is a spectrophotometric method.\(^{(103)}\) However, LC is most commonly used for the determination of aspartame.\(^{(104)}\) Sample preparation is minimal in labor for liquid samples, while solid samples are extracted with water and then injected onto the column. In another paper, it was reported that the detection limit by measuring native fluorescence was 0.01 mg l\(^{-1}\) of diet soft drinks.\(^{(105)}\)

### 8.3 Salicylates

Salicylates, which are esters or salts of salicylic acid, are natural compounds made by a variety of plants. They compete with aspirin for the same cellular binding sites in the body, providing similar actions to aspirin. They relieve pain and fever, but at the same time they can cause health risks such as intestinal bleeding or allergic reactions. A diet rich in fruits and vegetables may help prevent heart attacks as well as some cancers by providing healthy doses of salicylates. Therefore, there is an interest in the salicylate levels of both natural foods and food additives.

TLC has been used for qualitative analysis of salicylates in food. LC with UV detection or fluorescence detection has been used to monitor salicylates in food.\(^{(106)}\) While HPLC with UV detection suffered from interference problems, HPLC with fluorescence detection was sensitive and specific.

### 9 AMINO ACIDS

To analyze the amino acid composition of proteins, the protein hydrolysate has been applied to a cation-exchange column and ninhydrin derivatives of amino acids in the effluent are measured colorimetrically using a spectrophotometric detector. However, RPHPLC with a \(C_{18}\) or \(C_{8}\) column before or after derivatization of amino acids with \(o\)-phthalaldehyde (OPA) is convenient for detection using a fluorometric detector.\(^{(107)}\) This is because of simpler solvent systems required for eluting the amino acids from the column and quicker elution (less than 30 min) than ion-exchange chromatography. The phenylthiohydantoin (PTH)/RPHPLC can accurately quantify 5 pmol of 50-kDa protein, 2–3 times more sensitively than ion-exchange/ninhydrin detector systems.

Progress has recently been made in RPHPLC after pre-column derivatization. Rapid derivatization and direct injection without cleaning is now feasible by using 6-aminoquinolyl-\(n\)-hydroxysuccinidy carbamate to derivatize for fluorometric detection.\(^{(108)}\) By using phenylisothiocyanate for derivatization, a UV detector that is more popular on HPLC instruments can be used with similar detectability to fluorometric detectors.\(^{(109)}\) For the first time, detection of femtomolar amounts in various foods has been achieved by fluorometric detection of ninhydrin derivatives of amino acids.\(^{(110)}\)

### 10 ENZYMES

Despite the great potential of a broader application of fluorometry to enzyme assays, ALP and protease are the only enzymes reported in the recent literature concerning food analysis.
10.1 Alkaline Phosphatase

Proper pasteurization is a crucial process in the dairy industries. ALP (EC 3.1.3.1) is one of the indigenous enzymes found in raw milk.\textsuperscript{(112)} ALP activity has been used as an indicator for determining the adequacy of pasteurization of milk. ALP in milk is inactivated at temperatures slightly higher than necessary to kill non-sporing pathogenic bacteria.\textsuperscript{(113)} Therefore, the presence of ALP activity indicates either inadequate pasteurization or recontamination of already pasteurized milk with raw milk, thus causing a health hazard.

Different methods have been proposed to quantify ALP activity. Colorimetric methods have been adopted as an official method in the dairy industry. They use phenyl phosphates, such as \( p \)-nitrophenyl phosphate, or phenolphthalein monophosphate as a substrate, and ALP activity is then measured spectrophotometrically. The disadvantages of these approaches are complicated sample preparations such as protein precipitation, extraction, dialysis, and isolation of enzymatically formed products prior to analysis.

A fluorometric method has been developed lately.\textsuperscript{(114)} The method was adopted by the Association of Official Analytical Chemists (AOAC) in 1990.\textsuperscript{(114)} A fluorometric substrate, Fluorophos\textsuperscript{®}, loses a phosphate radical and converts to a highly fluorescent form of Fluoroyellow\textsuperscript{®}, when acted upon by ALP. The rate of fluorophore formation is monitored and the enzyme activity is expressed in mU L\textsuperscript{-1}. The method is rapid (3 min), sensitive, precise, and easy to carry out. It avoids interference and nonspecificity, and does not require long and complicated sample preparation. It has been applied to dairy products other than whole milk, e.g. skim milk, chocolate milk, and cream.\textsuperscript{(114)}

Considerable research has been conducted using this new Fluorophos\textsuperscript{®} method. It can detect ALP activity below the US legal limits in dairy products.\textsuperscript{(115)} ALP activity in pasteurized milk has been determined at various combinations of temperatures and time. Eckner\textsuperscript{(116)} reported a good correlation between ALP inactivation and pathogen inactivation. The Fluorophos\textsuperscript{®} method was favorably compared to the Australian standard method.\textsuperscript{(117)} Most of the papers published so far have reported that the Fluorophos\textsuperscript{®} method is fast, sensitive, and reliable.

ALP has also been widely used in ELISA, blotting techniques and in situ hybridization. The advantage of ATP is the good stability of the enzyme as well as the conjugates, high sensitivity, and the availability of fluorogenic and chromogenic substrates.\textsuperscript{(116)} The ELISA has been widely employed in many areas of food analysis. Fluorescent avidin and streptavidin are extensively used in the ELISA. Examples of applications can be found in many books and reports.\textsuperscript{(119)}

In a similar manner to ALP, acid phosphatase was also used to indicate the heating of cooked, boneless, non-breaded broiler breast and thigh meat.\textsuperscript{(120)}

10.2 Proteolytic Enzymes

In the dairy industry, proteolytic activity is a useful predictor of shelf life. During storage of raw milk, psychrotrophic bacteria become the dominant flora and produce heat-resistant extracellular enzymes. These enzymes can degrade fat and proteins, thereby adversely affecting the quality and shelf life of milk and dairy products.\textsuperscript{(121)} In cheeses, proteolysis during ripening greatly affects texture and flavor.\textsuperscript{(122,123)} It is extremely important to find the extent of proteolysis as results of cheese maturity, acceleration of cheese ripening, and/or selection of starter culture.\textsuperscript{(122)}

The degree of proteolysis in cheeses has been determined by assessing the amount of nitrogen-soluble compounds using various precipitants to remove insoluble proteins. Various methods used to extract soluble nitrogenous compounds were reviewed in recent papers.\textsuperscript{(123)} However, these methods are tedious and time-consuming. More rapid methods have been suggested to determine proteolysis by analyzing free amino acids. For the quantification of amino acids, chromatographic techniques similar to those as already discussed have been used. Fluorescamine was used for a postcolumn derivatization while OPA has been used for both pre- and postcolumn derivatizations.\textsuperscript{(124)}

In milk and dairy products, several methods are used to measure proteolysis.\textsuperscript{(125,126)} They are chemical (Kjeldahl) and spectrophotometric, such as UV, Hull, Lowry, dye binding, ninhydrin, trinitrobenzenesulfonic acid (TNBS), and fluorometric, such as OPA and fluorescamine. \( \alpha \)-Phthalaldehyde reacts with the \( \alpha \)-amino group of free amino acids and small peptides under alkaline conditions in the presence of a reducing agent and forms a fluorescent compound. The OPA reaction is more rapid and convenient than the TNBS method.\textsuperscript{(127)} The postcolumn OPA derivatization has also been applied to quantify free amino acids in cheeses.\textsuperscript{(128)}

A fluorescamine method used to determine proteolytic activity is based on the use of the fluorescent dye, which reacts specifically with proteins and amino acids of microbial cells. The fluorescamine method was compared with other methods, i.e. absorbance at 280 nm, TNBS assay, and the Lowry method.\textsuperscript{(129)} Each method was applied to the trichloroacetic acid soluble fraction of milk protein, which had been preliminarily digested with trypsin. The fluorescamine method was the most reliable and sensitive method among those four methods.
Proteolytic activity has also been determined using an FIA method. The amount of fluorescein released from enzymatic cleavage of the labeled protein used as a substrate is found to be directly proportional to the proteolytic activity. The method is rapid, sensitive, and suitable for routine determination.\(^\text{130}\)

### 11 MISCELLANEOUS

Histamine and histidine in tuna were determined by HPLC with a fluorescence detector after derivatization with OPA.\(^\text{131}\) Biogenic amines in food were determined by precolumn derivatization with 2-naphthoxyloxycarbonyl chloride.\(^\text{132}\) Eight heterocyclic carcinogenic amines in satay, a local delicacy in Singapore, were determined using HPLC by measuring their natural fluorescence.\(^\text{133}\) Nitrated polycyclic aromatic hydrocarbons in foods were determined by on-line reduction and HPLC.\(^\text{134}\)

Ethanol contents in low ethanol concentration drink and vinegar were determined by measuring intrinsic fluorescence of alcohol dehydrogenase.\(^\text{135}\) Fluorometric HPLC determination of ethylenediaminetetraacetate in foods was proposed by reacting with Zr and Alizarin Red S.\(^\text{136}\) Fluorometric determination of connective tissue in beef was discussed with regard to the relative direction of fluorescence measurement.\(^\text{137}\) The effect of pH on fluorescence formation related to fish deterioration was discussed.\(^\text{138}\)

The application of fluorescence polarization spectroscopy in food research has been reviewed by Marangoni.\(^\text{139}\) It was utilized in the determination, using microviscosity, of isotropic fluids such as edible fats and oils, and oil-in-water emulsion cores. The same method was also used for structural order determination of liposomes and biological membranes.

When Udenfriend’s book\(^\text{1}\) was consulted again, it was found that the applications mentioned in this article had not fully covered the analysis of some carbohydrates (e.g. hexoses, pentoses, sialic acid), aldehydes, ketones, steroids, and inorganic constituents (e.g. calcium, magnesium, zinc, aluminum, selenium, fluoride, ammonia, hydrogen peroxide) of foods. Thus, it is worth noting that many components in foods, other than those discussed in this article, can also be analyzed by fluorometry.

Infrared Spectroscopy, Gas Chromatography/Infrared in Food Analysis

Ranjana Mehrotra
National Physical Laboratory, New Delhi, India

Infrared (IR) radiation is usually defined as that electromagnetic radiation whose frequency is between 20 and 14,500 cm\(^{-1}\). Within this region of the electromagnetic spectrum, chemical compounds absorb IR radiation provided there is a dipole moment change during a normal molecular vibration, molecular rotation, and molecular rotation–vibration or from combinations, differences and overtones of the normal molecular vibrations. The frequencies and intensities of the IR bands exhibited by a chemical compound uniquely characterize the material and its IR spectrum can be used to identify and quantify a particular substance in an unknown sample. IR spectroscopy in both the mid-infrared (MIR) and near-infrared (NIR) regions is emerging as a qualitative as well as quantitative analytical technique with great potential in a wide range of applied areas. The prime advantage of IR spectroscopy in food applications is that once the instrument has been calibrated, several constituents in a sample can be measured rapidly and simultaneously. No sample manipulation is required. It is also applicable to on-line analysis in the food processing industries.

1 INTRODUCTION

All molecules are made up of atoms linked by chemical bonds. The movement of atoms and chemical bonds can be compared with that of a system comprised of springs and balls in constant motion. Their motion can be understood as being composed of two components, the stretching and bending vibrations. The frequencies of these vibrations depend on the nature of the particular bonds, such as C–H/C–O bonds.

IR radiation is usually defined as that electromagnetic radiation whose frequency is between 20 and 14,500 cm\(^{-1}\). Within this region of the electromagnetic spectrum, chemical compounds absorb IR radiation provided there is a dipole moment change during a normal molecular vibration, molecular rotation, and molecular rotation–vibration or from combinations, differences and overtones in the normal molecular vibrations. The frequencies and intensities of the IR bands exhibited by a chemical compound uniquely characterize that material and its IR spectrum can be used to identify and quantify a particular substance in an unknown sample. IR spectroscopy in both the far-infrared (FIR) region, MIR region and NIR regions. Each region of the spectrum plays a different role in analysis according to the different character of the transitions involved in each case.

The FIR region can be divided into three segments, the far-infrared (FIR) region, MIR region and NIR regions. Each region of the spectrum plays a different role in analysis according to the different character of the transitions involved in each case.

The FIR region extends from 20 to 400 cm\(^{-1}\). This region contains the bending vibrations of C, N, O and F with heavier atoms and additional bending
motions in cyclic or unsaturated systems. This region is useful for studying isomers, organometallics and organic compounds whose atoms are heavy and bonds are weak.

However, the region between 400 and 4000 cm\(^{-1}\) is the most attractive for chemical analysis. This MIR region corresponds to fundamental transitions in which one vibrational mode is excited from its lowest energy state to its first excited state. This region includes the frequencies corresponding to the fundamental vibration of virtually all of the fundamental groups of the organic molecules. These spectral lines are typically narrow and distinct, making it possible to identify and monitor a band corresponding to the specific feature. As a result, quantitative calibrations performed in the MIR are usually straightforward and robust.

The NIR region lies between the visible and the MIR region of the electromagnetic spectrum and is defined as the spectral region spanning the wavelength range 4000–14,500 cm\(^{-1}\). This region arises from transitions in which a photon excites a normal mode of vibration from ground state to the second or higher excited vibrational state (overtones) and transitions in which one photon simultaneously excites two or more vibrational modes (combinations). This region is often associated with hydrogen atoms, as in O–H, N–H and C–H systems. The NIR region is mainly used for quantitative analysis. Owing to short wavelength and high energy and hence high penetrating power, the region is very useful for biological samples.

2 INSTRUMENTATION

There are two different types of commercial instrument available for IR measurements: the dispersive/filter-based and the Fourier transform spectrometer. Each of these instruments works in a distinctly different manner.

2.1 Dispersive Spectrometer

Since 1940, dispersive instruments have been available for measuring IR spectra in the MIR and NIR regions. A dispersive instrument consists of a source, monochromator and a detector (Figure 1). The radiation source in most IR instruments is a globar lamp, which is made of silicon carbide in the MIR region and is a tungsten halogen lamp in NIR region. A dispersive monochromator utilizes either a prism made from materials such as sodium chloride, potassium bromide, cesium fluoride, or a grating. The purpose of a prism or grating is to enable the separation of continuous blackbody radiation into its component wavelengths. The grating used in dispersive IR spectrometers consists of parallel grooved lines ruled into a reflective metal surface. The detector mainly used in the MIR region is deuterated triglycine sulfate (DTGS) and in the NIR region is silicon (Si) and lead sulfide (PbS). Some instruments are dedicated to specific applications. In these instruments, a number of optical interference filters are used to select discrete wavelengths that can be impinged on the sample. The filters are selected to transmit wavelengths that are known to be absorbed by the sample constituents. The instrument inserts filters one at a time into the light beam to direct individual wavelengths of radiation onto the sample.

The resolution of a dispersive/filter-based IR spectrometer is a function of the size of the entrance and exit slits of the monochromator. Both transmittance and reflectance measurements are possible with this type of instrument.

2.2 Fourier Transform Infrared Spectrometer

The typical Fourier transform infrared (FTIR) spectrometer has three basic components: a source, a detector and a Michelson interferometer. The sources used in FTIR in the MIR region are a ceramic element and a silicon carbide rod, both operating at approximately 1100 °C. The ceramic element is a spiral wound nichrome wire coated with a ceramic material, which is heated when
current is passed. The second source, silicon carbide, is quite rugged and efficient, but because of large size and power dissipation, water-cooled or air-cooled housings are necessary. Most of the FTIR spectrometers have a silicon carbide element as source. In the NIR region a tungsten halogen lamp is mostly used. Two different types of detector are mainly used in FTIR in the MIR region: a thermal detector such as DTGS, and a pyroelectric detector and photoconductive detector, such as the mercury cadmium telluride (MCT) detector. The detectors used in the NIR region are silicon (Si) and lead sulfide (PbS).

The unique part of an FTIR spectrometer is the Michelson interferometer shown in Figure 2. IR radiation from the source is made parallel and strikes the beam splitter at an angle of 45°. The beam splitter transmits half the radiation striking it and reflects the other half. The transmitted and reflected beams leave the beam splitter at right angles and strike two perpendicularly placed plane mirrors (see Figure 2), one of which can move in a direction perpendicular to the plane, which return the two beams to the beam splitter. The two beams recombine at the beam splitter and show interference. Fifty percent of the beam reflected from the fixed mirror is transmitted through the beam splitter and the other 50% is reflected back in the direction of the source. The radiation, which emerges from the interferometer at 90° to the input beam and is called the transmitted beam, is then passed to the sample, and subsequently goes to the detector. The moving mirror produces an optical path difference between the two arms of the interferometer. This is called the retardation and is twice the displacement of the moving mirror from the equidistant point. If a monochromatic source like a laser is used, the radiant energy reaching the detector will vary as a cosine function of the retardation. The detector response will reach a maximum every time the retardation is an integral number of wavelengths of the radiation. At this time, the beams from the two mirrors combine at the beam splitter in phase and show constructive interference. If the moving mirror is then moved one quarter of a wavelength of radiation, the retardation is changed by one half of a wavelength. The beams from the two mirrors combine at the beam splitter one half of a wavelength out of phase for the beam going to the detector and show destructive interference. The detector response as a function of the retardation is called the interferogram. The spectrum is generated from the interferogram with the help of Fourier transform.

The main advantage of the FTIR spectrometer over the dispersive instrument is a high signal-to-noise ratio (S/N). This is because all the radiation frequencies reach the detector at the same time and the intensities of all the wavelength elements are analyzed simultaneously. Another advantage is that the spectrum can be recorded in less time.

3 SAMPLING TECHNIQUES

IR spectroscopy is a versatile analytical technique for qualitative and quantitative analysis of solids, liquids and gaseous samples.

3.1 Transmission Methods

Transmission spectroscopy is the oldest basic technique for sample analysis in the IR region. The method of analysis is based on the absorption of the IR beam by a sample at specific wavelengths. Solids, liquids and gases can be analyzed by transmission spectroscopy.

3.1.1 Solid Samples

Solid samples can be analyzed in the following forms:

- **KBr Disc** – A very popular technique for analysis of solids is the KBr disc. In this technique, a few milligrams of sample are finely ground with a mortar and pestle and then mixed with 50 to 100 parts of dry KBr powder. The mixture is placed in a special device and compressed into a disc at high pressure. This sinters the mixture and produces a clear transparent disc.
- **Mulls** – This method for solid samples involves grinding the sample and then suspending it in 1–2 drops of a mulling agent. This is followed by further grinding until a smooth paste is obtained. The paste so obtained is spread between two IR transmitting...
windows. The most commonly used mulling agent is Nujol (liquid paraffin).

- Films – Spectra of solids not soluble in a suitable solvent are best obtained in the form of capillary films. A large drop of the neat liquid is placed between two IR transmitting windows, which are then squeezed together and mounted in the spectrometer in a suitable holder. Plates need not have high polish, but must be flat to avoid distortion of the spectrum. Thin films can often be prepared by casting a thin film from a solution of the sample and evaporating off the solvent. The film may be cast onto an IR transparent window or onto a suitable support from which it can be readily peeled. The film so obtained can be analyzed by using a film holder.

### 3.1.2 Liquid Samples

The easiest samples to run on an IR instrument are those in the liquid state. Slightly viscous samples can be squeezed between the two-polished IR transmitting plates and run as thin films. If the liquid is not viscous, fixed or variable pathlength can be used. Fixed pathlength sealed cells are useful for volatile liquids but cannot be disassembled for cleaning. Variable pathlength cells (Figure 3) are demountable so that the windows can be cleaned. An insoluble polymeric film is used as a spacer between two IR plates. Spacers are available in a variety of thicknesses allowing one to use various pathlengths. These cells are filled with the help of a syringe. An important consideration in the choice of IR cells is the type of window material. The material must be transparent to the incident IR radiation. Some commonly used IR materials are given in Table 1.

#### 3.1.3 Gas Samples

Gas cells are essentially gastight containers fitted with IR transparent windows to enable the radiation to enter and exit the container, and a means for introducing, pressurizing and evacuating the gas. The gas cells are mainly constructed from borosilicate glass or stainless steel.

ATR, attenuated total reflectance.
steel with windows at each end. The gas density is many times lighter than liquid and solid at standard temperature and pressure. Therefore, transmission spectroscopy of gases requires cells with a longer pathlength than those used for liquid or solid analysis. For higher concentrations, a 10-cm long gas cell is generally used. For low concentrations, a long pathlength gas cell is used (few meters). Long pathlength is achieved in a short space by using a multipass cell in which the IR beam is bounced through the sample several times in order to obtain the desired pathlength. A typical gas cell is shown in Figure 4.

3.1.4 Cell Thickness Measurement

Cell thickness measurement can be done by an interference fringe method. This method is ideally suited to cells whose windows have a high polish. If an empty cell with parallel windows is placed in the spectrophotometer and a wavelength range scanned, an interference pattern is obtained which is as close as possible to the 100% line. The cell thickness is calculated from the expression, Equation (1),

\[ b = \frac{n}{2} \eta_d (v_1 - v_2) \]  

where \( n \) is the number of fringes (peaks or troughs) between two wavenumbers \( v_1 \) and \( v_2 \), and \( \eta_d \) is the refractive index of the sample material. If the measurements are made in wavelength, Equation (2) is:

\[ b = \frac{n \lambda_1 \lambda_2}{2} \eta_d (\lambda_1 - \lambda_2) \]  

where \( \lambda_1 \) is the starting wavelength and \( \lambda_2 \) the ending wavelength. The fringe method also works well for measurement of film thickness.

3.2 Reflectance Methods

Reflectance techniques are mainly used for samples which cannot be analyzed by conventional transmittance methods.

3.2.1 Specular Reflectance

When a beam of IR radiation is focused on to the sample, two types of reflectance may occur, namely specular and diffused. Specular reflectance occurs when the reflected angle of IR radiation equals the angle of incidence. The amount of light reflected depends on the angle of incidence, the refractive index, surface roughness and absorption properties of the sample. This technique is mainly used for surface measurements from the shiny surface of the sample.

3.2.2 Diffuse Reflectance

Diffuse reflectance mainly occurs from rough surfaces. As shown in Figure 5, the source radiation penetrates one or more particles in the sample and then is diffusely reflected in all directions. This radiation is collected and measured by a spectrophotometer. In diffuse reflectance the spectrum is processed using the Kubelka and Munk function, this changes the reflectance spectrum into one resembling a linear absorbance spectrum given as, Equation (3),

\[ F(R_t) = \frac{(1 - R_t)^2}{2R_t} = \frac{c}{k} \]  

where \( R_t \) is the reflectance of a thick scattering layer, \( c \) is the concentration and \( k \) is the molar absorption coefficient.

Many food samples give diffuse reflectance spectra. These include powders, fibers or matt surface samples. The spectrum is very sensitive to the particle size, which

Figure 4 Gas cell.

Figure 5 Representation of diffuse reflectance.
affects the scattering of radiation. If the particle size is not uniform, spectral distortion may occur.

3.2.3 Attenuated Total Reflectance

Attenuated total reflectance (ATR) spectroscopy has been one of the most popular sampling techniques employed for biological samples. ATR spectroscopy utilizes the phenomenon of total internal reflectance (Figure 6). A beam of IR radiation entering a crystal will undergo total internal reflection when the angle of incidence at the interface between the sample and crystal is greater than the critical angle. The critical angle is a function of the refractive indices of the two surfaces. The beam penetrates a fraction of a wavelength beyond the reflecting surface and when a material that absorbs radiation in very close contact with the reflecting surface, the beam loses energy at the wavelength where the material absorbs. The resultant attenuated radiation is measured as a function of wavelength that gives rise to the absorption spectral characteristics of the sample.

In an ATR crystal, a standing wave is established near the surface of the crystal. The amplitude of the electric field decreases exponentially with distance from the surface of the ATR. The distance at which the field reaches 1/e of its initial magnitude is defined as the penetration depth \( d_p \). The magnitude of \( d_p \) depends on the wavelength of the radiation, \( \lambda \), the refractive index of the ATR crystal, \( n_p \), the refractive index of the sample, \( n_s \), and the angle of incidence of the beam at the surface of the IRE, \( \phi \), according to Equation (4)

\[
d_p = \frac{\lambda}{2\pi} n_p (\sin^2 \phi - n_s^2)^{1/2}
\]

where \( n_{sp} = n_s/n_p \) (\( n_s < n_p \)).

The crystals used in ATR cells are made from materials which have low solubility in water and are of high refractive index such as zinc selenide (ZnSe), germanium (Ge) and thallium/iodide (KRS-5). Solid samples, like powder, can be put directly onto the ATR crystal and compressed to ensure good surface contact. It is also possible to deposit materials onto the surface of the ATR crystal by applying drops and then evaporating the solvent. Liquid samples can be poured directly into the ATR trough.

3.3 Fibre Optic Probe

An MIR fibre optic ATR probe is the most exciting new sampling technique available for IR scientists. This is extremely useful for analyzing samples that are at a remote location or for analyzing samples that are not of the optimum shape or size to fit into the sample compartment. NIR fiber optic transmittance and diffuse reflectance probes are also available for on-line process analysis.

4 QUANTITATIVE ANALYSIS

4.1 Beer–Lambert Plot

Quantitative measurements in absorption spectroscopy are based on the fundamental relationship between absorbance, pathlength and concentration. The relationship known as Beer’s law is given by Equation (5)

\[
A(\nu) = k(\nu) \times b \times c
\]

where \( A(\nu) \) is the absorbance at frequency \( \nu \), which is proportional to the product of the pathlength of the IR beam through the sample \( b \) and concentration of the sample \( c \); \( k(\nu) \) is the proportionality constant and is defined as the absorptivity of the substance being analyzed at frequency \( \nu \) and is a measure of the substance’s ability to absorb IR radiation of that frequency and to translate it into molecular vibrational energy.

4.2 Classical Least Square Method

When only a single IR component is present in a sample or in other words when an isolated nonoverlapped band can be identified, Equation (1) can be used to develop a quantitative method for determining the component’s concentration. However, in complex systems like food products, several compounds are usually found. In this case multicomponent quantitative analysis becomes important. Beer’s law has to be modified and written as, Equation (6)

\[
A_{\lambda 1} = K_{\lambda 1} C_a + E_a
\]

where \( C_a \) is the concentration of component \( A \), \( A_{\lambda 1} \) is the absorbance at wavelength 1, and \( E_a \) is the error in the concentration predicted by least squares fit line and actual concentration. According to Equation (6), the concentration is a function of the absorbances at a series of given wavelengths. This method is also called the K

![Figure 6](image-url)
matrix method. Using matrix algebra, Equation (6) can be solved for a best fit least square line to the data. Once the equation has been solved for the $K$ matrix, it can be used to predict concentrations of unknown samples. One disadvantage of this technique is that the equations must be calibrated for every component in the mixture. If the concentration of one component is omitted, the predicted absorbance will be incorrect. In other words, the classical least square (CLS) technique can only be applied to systems where the concentration of every component in the mixture is known. In addition, there must be no significant interactions between the different components when they are mixed together. For example, when two liquids are mixed together, there may be some interaction that occurs to create a small amount of new compound. This new compound will have a spectrum of its own, and thus, it will also have a different set of absorptivity coefficients from the other two components. If the concentration of this new compound is not included in the calibration, the calculated $K$ matrix will not reflect the absorptivities of this component and predictions of unknown will be in error. Typically the CLS calibration method is most useful when applied to samples which have minimal intercomponent interactions such as many gas phase mixtures.

### 4.3 Inverse Least Square Method

As discussed in the previous section, if the concentrations of all the components in the mixtures are not known, the CLS method does not give very good calibration equation and there may be a significant amount of error. In these cases, the inverse least square (ILS) method is used. Beer’s law can be rearranged and written as Equation (7)

$$C_a = A_{\lambda}P_{\lambda,1} + E_a \quad (7)$$

where $C_a$ is the concentration of component $A$, $A_{\lambda}$ is the absorbance at wavelength 1, and $E_a$ is the error in the concentration predicted by the least squares fit line and actual concentration. According to Equation (7), the concentration is a function of the absorbances at a series of given wavelengths. This method is also called the $P$ matrix method. This method is the best method for almost all quantitative work as knowledge of the sample composition is not required.

This method also has some disadvantages. Owing to the dimensionality of matrix equations, the number of selected wavelengths cannot exceed the number of training samples. This problem can be overcome by measuring many more samples to allow additional wavelengths. However this causes the problem of collinearity and the solution becomes unstable with respect to each component.

### 4.4 Partial Least Square/Principle Component Analysis

Partial least square (PLS) and principal component regression (PCR) are the most widely used multivariate calibration methods used in food science. Both PLS and PCR methods make use of the inverse calibration approach, where it is possible to calibrate for the desired component while implicitly modeling the other sources of variation. In both methods, the inverse problem is solved by replacing the original variables with linear combinations of the variables known as factors. The difference between the PCR and PLS factor analysis methods lies in the fact that PCR performs the factor analysis in such a way that the factors describe only the variance in the calibration spectra. Variations in the spectra that are not related to the concentration of the analyte may receive large weight in the analysis. The PLS method, however, has been designed to extract factors that simultaneously account for the variance in the spectral data and correlate with analyte concentrations. Thus, better concentration prediction ability is expected for PLS relative to PCR when a portion of the variation in the spectral data does not correlate well with concentration variations. Mathematical descriptions of both methods are given elsewhere.

### 4.5 Calibration

The first step in calibrating an instrument, for a particular application, is to select a set of calibration or training samples. The samples are representative of the product that has to be analyzed. Training samples should cover the full range of the product and should have a relatively uniform distribution of concentrations across that range. The calibration samples must be analyzed by the traditional reference method normally used for that constituent. The spectral data are obtained for each training sample with the IR instrument at all available wavelengths. All the data are stored in the computer memory and quantitative analysis is performed on the data.

Quantitative analysis of the spectral data is a three-step procedure. The first step is the calibration, in this the regression model that best relates the IR spectral data to the reference data is determined. The second step is the validation, in which known samples are used to ensure that an overfitted solution has not been obtained and to establish the robustness of the calibration. After the calibration has been established, the third step is prediction with an unknown sample.

The greatest error sources in any calibration are generally reference laboratory error, repack error (non-homogeneity) and nonrepresentative sampling in the calibration set. Performing an in-house audit of procedures, equipment and paying particular attention on sample preparation can reduce these error sources.
4.6 Error Analysis

The root mean square error and the multiple correlation coefficient are both ways of calculating how well the calibration equation fits the data. The values of the root mean square difference (RMSD), which is an indication of the average error in the analysis, for each component is, Equation (8)

$$\text{RMSD} = \frac{1}{N} \sum_{i=1}^{N} (A_i - B_i)^2$$  

(8)

and the square of the correlation coefficient ($R^2$), which is an indication of the quality of fit is, Equation (9)

$$R^2 = \frac{\sum_{i=1}^{N} (A_i - C)^2}{\sum_{i=1}^{N} (B_i - C)^2}$$  

(9)

where $A_i$ is the actual concentration of the analyte in the sample $i$, $B_i$ represents the estimated concentration of the analyte in the sample $i$, $C$ is the mean of the actual concentrations in the prediction set and $N$ is the total number of the samples used in the prediction set.

Normally a correlation coefficient can have values between 0 and 1. The value close to zero indicates that the calibration is failing to relate the obtained values to the reference values. As the correlation coefficient increases the obtained values become better and better indicators of the reference values until, when the correlation coefficient reaches unity, the obtained values and the reference values are identical in all cases.

5 FOOD APPLICATIONS

IR spectroscopy in both the MIR and NIR regions is emerging as a qualitative as well as quantitative analytical technique with great potential in a wide range of applied areas. IR spectroscopy mainly in the NIR region is widely used in food and agro-based industries. A detailed bibliography has been published in conference proceedings\(^3,4\) and a review article\(^5,6\).

5.1 Analysis of Water

IR spectroscopy in the NIR region is considered to be a universal approach for determination of moisture content in food products because water has strong absorption in the NIR region providing the sensitivity needed for accurate determination. In addition, changes in the water absorption band are reflective of chemical interactions with other molecular species in the samples, and therefore it can be used for analysis of other food constituents, which do not have their own characteristic absorption bands. The spectrum of water consists mainly of two composite bands, the first overtone at 1450 nm and combination band at 1940 nm at room temperature (Figure 7). These bands are influenced by changes in the hydrogen bonding. The O–H band position and patterns differ from one food product to another. The IR spectrum of water is also a function of temperature. As a function of changing temperature, the relative properties of the individual bands making up these composite bands change, resulting in a shift in the band position. The influence on water absorption caused by variation in temperature has been used to develop a calibration equation with temperature compensation to determine the brix value in peaches.\(^7\)

The changes in chemical composition of food products during aging affect the states of hydrogen bonding of O–H bonds present in the water content. The staling and aging of food products, for example, wheat flour is easily studied using NIR spectroscopy.\(^8\)

5.2 Analysis of Sugars

The sugar cane refinery depends on constant monitoring of in-process and finished product streams in order to maintain process control, plant efficiency and on-going product quality. Testing of sugar cane for sucrose content and other common constituents like glucose and fructose has traditionally been done in sugar industry by a variety of gravimetric and wet chemical methods. While these standard techniques are reliable, they are often time-consuming, operator dependent and involve the use of hazardous reagents. Second, the most commonly used technique in the sugar industry – sucrometry/polarimetry – is not a true indicator of

![Figure 7](image-url) NIR spectrum of water at room temperature.
sucrose content and does not provide the concentration of individual components (sucrose, glucose and fructose) present in the sugar cane juices. More complete analytical methods are desired for better characterization of sugar mixture, which can readily be adopted for on-line work.

Quantitative determination of the main constituents of a sugar mixture can be carried out by IR spectroscopy. Different types of sampling techniques can be adopted for analysis of sugar cane juices and sugar cane solids in both the MIR and NIR regions. The juices can be handled by ATR sampler in the MIR region. Typical spectra of sugar cane juices and syrup obtained in the MIR region using the ATR accessory are shown in Figure 8. It is important to identify the peaks of different sugars by taking the spectra of pure components individually (Figure 9, Table 2). For quantitative analysis, different statistical methods can be used to obtain calibrations for synthetic mixtures of sucrose, glucose and fructose in concentration ranges typically encountered in sugar cane juice. The calibrations can be performed on real sugar cane juice samples for better results. In this case, the reference values of the training set can be obtained by traditional chemical methods.

A diffuse reflectance accessory in the NIR region works best for sugar cane solids. Figure 10 shows the spectrum obtained for a prepared cane sample in diffuse reflectance mode. The water absorption bands at 1450 nm and 1930 nm mainly dominate the spectrum. The O–H band absorption is masked beneath the water O–H vibrational signal. The main region used for sugar analysis is 2000–2500 nm. Another region 1600–1900 nm can also be exploited for quantitative work. Particle size plays a very important role while analyzing solid samples. The solid sample should be properly ground and homogenized for accurate results.

### 5.3 Analysis of Oils and Fats

Studies on oils and fats can be strongly profiled by IR spectroscopic techniques because oils are mainly composed of lipids, which have strong characteristic absorption owing to vibrations of the carbonyl group and hydrocarbon chain in the MIR region.

Several different approaches have been used for qualitative and quantitative analysis of oils and fats. In the...
MIR range the ATR sampling technique is mainly used either with pure samples or their solutions in solvents like ethy leth,\textsuperscript{(11)} CaF\textsubscript{2} flow cells with pathlengths of 0.1–1 mm are also applicable. Several accessories have also been designed for analyzing oil on-line using NaCl or KBr discs.\textsuperscript{(12)} A fiber optic probe with chalcogenide fiber equipped with a two reflection ZnSe ATR crystal has also been designed and spectra can be measured simply by immersing the probe in the oil sample.\textsuperscript{(11)}

Beside characterization of different edible oils,\textsuperscript{(13)} detection of adulterations,\textsuperscript{(14)} determination of degree of unsaturation,\textsuperscript{(15)} determination of cis and trans isomers,\textsuperscript{(16)} fatty acid contents and total solid fats,\textsuperscript{(17)} and monitoring auto-oxidation of oils and fats\textsuperscript{(18)} are some of the interesting applications of IR in the area of oils and fats.

The characterization and discrimination between different oils is based on some characteristic absorptions, mainly asymmetric C–O stretching frequencies of the ester grouping (C−O−C) that appear around 1300 cm\textsuperscript{−1} and asymmetric C−O stretching of the O−C−C group that appears around 1000 cm\textsuperscript{−1} (Table 3). FTIR along with chemometric techniques has made the classification of a large number of commercially available vegetable oils and margarines possible.\textsuperscript{(19)} Using a sealed fixed pathlength (NaCl) cell, it is possible to distinguish edible oils from other oils according to their vegetable origin.\textsuperscript{(13)} Analysis was based on determination of cis and trans double bond content and detection of impurities. Absorbancies corresponding to the cis double bond content are predominately responsible for this discrimination. Partially hydrogenated vegetable oil can be distinguished through trans C=H bending absorbance. Detection of impurities in sesame oil present in the trans form like lignin, sesame, sesamolin and sesamol and so on has been possible using their characteristic absorption in the fingerprint region.

The NIR region has also been widely used in studies of fats and oils. Even though well-resolved bands are very rarely obtained and spectra consist of broad overlapping bands which cannot be assigned to a single chemical. But with the help of chemometric techniques, it is possible to analyze biological samples especially food products, qualitatively and quantitatively, using NIR spectroscopy.

Determination of cis and trans double bond content and detection of impurities can be attempted by NIR reflectance spectroscopy. Vegetable oils like cottonseed, peanut, soyabean and canola are differentiated using discriminate analysis in NIR region.\textsuperscript{(20)} Wavelength regions from 1600 to 1800 nm and from 2100 to 2200 nm are selected for analysis since most differences in the NIR spectra patterns of oils are evident in these regions. Using the second order spectra, it is possible to separate the spectra of different vegetables. Choosing the same selected wavelengths and using discrimination analysis it is possible to classify unknown samples. The spectral region 1600–2200 nm of oils contains information about the fatty acid composition. The bands assigned to straight carbon chains are cis double bonds and are mainly located here. By applying principal component analysis (PCA) on the standardized full NIR spectral data of this region, classification of vegetable oils related to the fatty acid composition can be performed rapidly and easily.

### 5.4 Analysis of Milk and Dairy Products

Milk, butter, cheese, milk powder and some special milk-based dietary foods like those for babies, constitute the wide range of dairy products where the quantitative analysis of various constituents is desired. The main ingredients of interest to the dairy industry are butterfat and protein. In dried milk powders and special foods, determination of moisture and lactose is also very important. This forces industry to test thousands of samples. IR spectroscopy is now being widely used by the dairy industry as an analytical technique for various constituents. It is now an established AOAC (Association of Official Analytical Chemists) method for determination of fat, protein and total solids in liquid milk samples.

The casein content in raw milk samples has been determined using the FTIR spectroscopic method. A flow cell maintained at 40°C is used as a sampler, the milk samples are homogenized and absorption spectra are collected in the MIR range. The spectral bands of C–H and amide are correlated with the concentration of casein. PLS analysis and PCR are used for quantitative analysis.\textsuperscript{(21)}

Besides quantification of fat, protein and lactose in milk, IR spectroscopy in the MIR region also finds
application in analysis of milk fat, like determination of the trans fatty acid content in solid samples, milk powder and cheese.\(^{(22)}\) IR absorption spectroscopy does not find much use since blending and homogenizing the solutions of cheese and powder milk in water has become mandatory. IR reflectance spectroscopy mainly in the ATR mode, is used for these samples.

Reflectance spectroscopy is mainly used in the NIR region. Analysis of raw milk for measuring the composition in terms of fat, protein, lactose and total solids is an established method. Figure 11 shows the spectra of milk and water. As shown in Figure 11, the broad and intensive absorption bands of water overlap the absorption bands of protein and fat in this region. This overlap makes it difficult to correlate specific bands to fat and protein. These bands can be seen after transforming the raw data to second derivatives (Figure 12). Table 4 gives the NIR bands assigned to fat, protein and lactose in milk. Another problem is the hindrance to spectral deformation caused by scattering by fat globules. By applying PCA to the NIR spectra, it has been possible to assign some specific wavelengths to fat, protein, and lactose and to discriminate between the samples.\(^{(23)}\)

NIR spectroscopy has also been applied to the analysis of dried products for fat, moisture and protein to obtain the right composition mixture for special products. Because of uniform particle size, diffuse reflectance measurement in the case of spray dried products are much more suitable.\(^{(24)}\)

Cheese is another important dairy product. It is difficult to analyze using IR spectroscopy because of differences in processing, physical and chemical composition, and the high level of moisture and milk fat. However, few sampling techniques have been standardized for the reflectance mode to determine moisture, fat and salt content in cheese. A homogenized sample of processed cheese has been analyzed using the ATR technique.\(^{(25)}\) The bands at 1735 cm\(^{-1}\), 1244 cm\(^{-1}\) and 1165 cm\(^{-1}\) (Figure 13, Table 5) assigned to ester groups in fats are used for quantitative determination of fats. For protein content, the 1545 cm\(^{-1}\) band is more suitable since the 1640 cm\(^{-1}\) band is partly due to proteins and partly due to water.

Reflectance and transmittance measurements on grated cheese samples and also on intact samples using a fiber optic probe can be successfully used for quantitative analysis of fat and moisture content.\(^{(26)}\) The composition of butter with respect to moisture and the solids nonfat content can also be determined using NIR spectroscopy.

Another important application of IR spectroscopy is the detection of adulteration. Foreign fat adulteration in dairy products, butter and margarine can be done by studying the fatty acid profile of their NIR spectra.\(^{(27)}\) NIR spectroscopy is also useful for characterization of spectral variations induced by the presence of different kinds of contaminants in milk.\(^{(28)}\) This can be used to predict the addition of foreign substances to milk.

5.5 Analysis of Beverages and Juices

The IR technique is useful for determination of different constituents in different types of fruit juices and beverages. The percentage of absolute alcohol, methanol and other higher alcohols in alcoholic beverages like beer, wine, whiskies and brandies can be estimated using both MIR and NIR spectroscopy. A procedure has been proposed for ethanol determination in the vapor phase in the MIR region. The method is based on injection of small volumes of untreated samples into a heated pyrex glass reactor in which, at a temperature between 80 and 100 °C, the ethanol is volatilized and introduced by means of an FTIR spectrometer. By measuring the area of the flow injection, the recording obtained from the absorbance of transient signals in the wavenumber range between 1150 and 950 cm$^{-1}$, allows direct quantification of ethanol without the water background problem or interference from sugars. The method has been applied from low alcohol beverages to wines and spirits.$^{(20)}$ The important bands of interest in the case of alcohols are C–O stretching (1000–1300 cm$^{-1}$) and O–H stretching (2500–3650 cm$^{-1}$), which are mainly used for quantitative analysis.

The ATR sampling technique in the MIR region is used for quantification of ethanol and methanol in different varieties of whiskies. Figure 14 shows the spectrum of a mixture of water–methanol–ethanol–acetone, after subtracting the dominant water absorption band, to characterize successfully the peaks that are due to each component.$^{(30)}$ Calibration has been performed with a large number of synthetic samples. The predicted values match closely the reference values obtained by chemical methods with 99.9% accuracy. Besides quantification using PCR or PLS analysis, it is also possible to determine molecular structure from the vapor phase FTIR spectra and set up a discriminating rule that classifies alcoholic and nonalcoholic beverages.$^{(31)}$

A fiber optic transmission probe working in the NIR region can also be used to estimate ethanol in alcoholic beverages as well as during the timespan of a fermentation process.$^{(32)}$ A silica optical fiber of specific design can be used in-line in a process plant and it is possible to transmit NIR radiation in the 1–2 µm waveband over fiber distances of up to 1–2 km for process analysis and to determine ethanol percentage.$^{(33)}$

Quantitative analysis of individual sugars and acids in fruit juices has been performed both in the MIR and NIR regions using different sampling techniques. The ATR sampling technique is used for estimation of sugars and organic acids in apple juices in the MIR region. The spectral region 900–1200 cm$^{-1}$ encloses the absorption bands for all sugar components (Figure 9). A typical spectrum of apple juice is shown in Figure 15. Calibration has been performed on synthetic solutions using PCR and PLS algorithms.$^{(34)}$

5.6 Analysis of Grains

Application of IR spectroscopy to the evaluation of essential nutrients in food and agricultural commodities is being extensively explored in the area of grains and cereals. In the MIR region, the ATR sampling method can be used for protein, starch and carbohydrate analysis. The main regions of interest are listed in Table 6. The sample must normally be ground prior to analysis. The requirement for grinding must be related to the heterogeneity of sample and also to the particle size distribution.

However, the main contribution to evaluation of grains is made by NIR spectroscopy. The technique is being used to screen breeding and commercial samples for more desirable concentrations of constituents, which relate to the quality desired or preferred by processors and consumers. In addition to protein and moisture content, NIR spectroscopy is used to determine hardness, sieving test ash, color, starch damage, water absorption and loaf volume in wheat or flours\(^{35}\) or amylase content in rice.\(^{36}\) The beer-making potential of barley\(^{35}\) and the degradability of barley forages\(^{37}\) is also being judged by NIR spectroscopy. It can determine the quality of oil seeds and legume grains for degree of saturation and composition.\(^{38}\)

Initially NIR spectroscopy was applied to determination of moisture, protein, lipid and bran in wheat, but now a classification system based on spectral analysis has been developed which can differentiate between different varieties. Two-dimensional correlation spectroscopy across the MIR (Figure 16) and NIR (Figure 17) regions using correlation between amide I C=O/N–H stretch and phenolic stretch in the MIR with traditional starch C–O–H at 2104 nm in the NIR is used to distinguish winter from spring wheat.\(^{39}\)

The NIR image processing technique using a charge-coupled device (CCD) camera has been used for discriminating between varieties of rice giving around 90% accuracy. Sampling cells, which can be used

to grain a single rice kernel and measure the spectra, are used to predict the illegal mixture over two varieties.\(^{40}\) To determine moisture, a solvent extraction method has been used which is based on shift in the water band caused by variation in water content in an organic solvent like \(N,N\)-dimethylformamide and dimethylsulfoxide.\(^{41}\)

### 5.7 Analysis of Meat

Fat, protein and moisture contents of meat are very important and are commonly being obtained by the extraction–rinsing solvent method. NIR reflectance is a rapid method for determining the composition of meat. The residues from extracts of pork meat after being washed and dried were considered. The second derivatives of the spectra were recorded. The second derivative minimum/maximum peaks of protein are observed at 2408 nm and 2338 nm, while minimum/maximum peaks of fat are at 1212 nm, 1284 nm, 2204 nm and 1188 nm. Moisture shows minimum/maximum peaks at 1734 nm, 1774 nm, 2290 nm, and 1698 nm in the second derivative spectra recorded in the NIR reflectance mode.

In another experiment an 11 filter NIR transmittance analyzer (Meatspec analyzer) is used, in the 825–1075-nm range, to analyze two different types of meat samples, beef and pork.\(^{42}\) A system based on the use of PCA has been devised for testing the identity and the homogeneity of the samples. The system checks the spectral characteristics of the sample and rejects any sample which shows a deviation from the mean of all samples that is greater than a previously defined specification.

### 6 GAS CHROMATOGRAPHY/INFRARED SPECTROSCOPY

Gas chromatography (GC) for separation of volatile components of a mixture is an important tool for analytical chemists. FTIR has arisen as an important detector for gas chromatographic elutes. GC elutes are generally samples ranging from a few tens of micrograms to less than a nanogram. An FTIR spectrum interfaced to a gas chromatograph provides structural information about GC elutes. The FTIR offers a real time and nondestructive IR chromatographic detection of elutes.

#### 6.1 Gas Chromatography/Infrared Instrumentation

A gas chromatography/Fourier transform infrared (GC/FTIR) system consists of mainly a gas chromatograph, FTIR spectrophotometer, lightpipe, detector and computer. A schematic diagram is shown in Figure 18.\(^{43}\)

The FTIR spectrophotometer is generally at low resolution (8 cm\(^{-1}\)), the bandwidth of gaseous components being generally large owing to contributions from rotational transitions. A stable IR source is generally used since the source energy through the light pipe is cut to about 10%. A narrow band 700–4000 cm\(^{-1}\) MCT detector is commonly used. The spectral range is sufficient for detection of most of the compounds. The light pipe, the interface between GC and FTIR, is the most important component and is generally made from quartz. Its dimensions are based upon the width of GC peaks or, in other words, the type of GC column.

A range of GC techniques is applicable to the GC/FTIR system. Capillary column GC gives better chromatographic resolution and efficiency but has lower loading capacity. Use of capillary columns with a 0.5–1 µm film coating is currently very popular.

For higher loading capacity, packed columns are generally used. Certain other modifications have also been used. One of them is a matrix isolation technique in which the GC elutes are trapped in a frozen matrix of argon atoms. IR radiation is focussed upon a frozen sample and the reflection absorption spectrum is collected. The technique is more sensitive and gives high S/N. The chromatogram can also be frozen on an IR window kept at low temperatures and the spectrum can be collected in transmission mode. The data processing system collects information from an interferogram and processes to create the chromatograms.\(^{44}\)

#### 6.2 Applications of Gas Chromatography/Infrared Spectroscopy

The applications of gas chromatography/infrared (GC/IR) spectroscopy are versatile. The area of food analysis and product safety is of prime importance. A major field for the application for GC/FTIR is in the identification of important food constituents or for trace contaminant analysis.
The GC/FTIR technique is mainly used for identification of aroma and volatile components. Coffee and chocolates are important consumer products. Flavor is their important quality parameter. The aroma from a coffee plant can be analyzed using the GC/FTIR technique.\(^{(45)}\) Nitrogen gas is first passed through a chamber containing coffee berries followed by a trap for concentrating the aroma components. A specially designed desorption–injection apparatus is used to deposit the concentrates on to the GC column for identification using GC/FTIR. With this technique, it is possible to identify various compounds in the aroma. Headspace GC is also used for monitoring volatiles in beverages. Heating the sample at 100°C, the vapor is compressed and introduced onto a gas chromatograph equipped with a flame ionization detector (FID) that analyzes the volatiles from coffee samples. The volatile species including esters, aldehydes, ketones, acids, amines, alcohols and monoterpenes are effectively separated by GC and classified by FTIR identifying alcohols, esters and the C=O stretch vibration region is useful for esters, aldehydes and ketones. The C–O stretch region, 1300–1000 cm\(^{-1}\), is used for identifying alcohols, esters and the C–N stretch vibration of amines. The 2800–3000 cm\(^{-1}\) region is selected for aliphatic hydrocarbons and 3000–3140 cm\(^{-1}\) for unsaturated hydrocarbons.\(^{(46)}\)

GC/FTIR has tremendous power in discriminating between geometrical isomers. The technique finds use in analysis of essential oils that contain a mixture of geometrical isomers. The technique also has high sensitivity for carbonyl and hydroxyl functionalities present in substances responsible for imparting flavor and fragrance to these essential oils. Using GC/FTIR, more than 260 components are detected in peppermint oil extract.\(^{(47)}\)

Another novel and interesting application is to check the freshness of food products. Many components are shown to be produced in trace amounts during staling of food. One such component, ethyl carbamate is considered to be a carcinogen and is produced during the fermentation process. GC/FTIR is a useful analytical technique for its powers of detection in beverages and foods. An internal standard method using ethyl carbamate isotopically labeled with \(^{13}\)C and \(^{15}\)N in less than 1-mg quantities is used. The standard is added to whisky and the validity of technique in detecting <1-mg ethyl carbamate is checked.\(^{(48)}\)

### 7 ADVANTAGES AND LIMITATIONS

The prime advantage of IR spectroscopy is that once the instrument has been calibrated, several food constituents in a sample can be measured rapidly and simultaneously. No sample manipulation is required. It is also applicable for on-line analysis in the food processing industry. Table 7 gives a comparison of the IR technique with other techniques.

There are a few limitations to working with IR spectroscopic methods. The main drawback is that the technique is indirect, based on reference values, it is subjected to errors. Samples of biological origin are especially complex and difficult to handle. Even minute changes in absorbance indicate large concentration changes and the bands representing the components are overlapped by interfering bands. As a result the detection limit of the technique cannot be reduced beyond 0.5–1.0%. The analysis is also affected by the differences in performance and the type of calibration program used in a particular application.

In the area of food applications solid sampling is often the method of choice by users. The diffuse reflectance technique is prone to error. The intensity of diffusely reflected energy is dependent on sample packing, density, sample crystalline structure, refractive index, particle size distribution, and absorptive qualities of the material. In addition, errors introduced in laboratory reference methods, nonhomogeneity of samples introduced during packing or repacking and also the variance in sample population are other noticeable drawbacks associated with the IR technique. All these errors add up to cause a large variation in analysis. Quantitative analysis in IR spectroscopy also depends on how well the Beer–Lambert law is fulfilled. The large concentration ranges and spectral abnormalities introduced by

factors like those discussed above cause nonlinearity in Beer’s law.
Performing an in-house audit of procedures and equipment and paying particular attention to sample preparation can reduce these sources of error.

REFERENCES

The term lipid encompasses a great host of compounds (e.g. fatty acids (FAs), mono-, di- and triglycerides), that are almost ubiquitously present in foods; their characterization and quantification is then of importance for an analytical chemist.

The first step for an accurate analysis is sample preparation: choosing an appropriate solvent or phases can isolate one particular class of lipid from a sample [a good separation of classes can be accomplished by thin-layer chromatography (TLC)]; obviously, the sample pretreatment will be governed by the determinations to follow. Indeed, nowadays, there is a host of techniques, mainly chromatographic, for lipid analysis. TLC is a rapid way to gather information about the sample (presence of conjugated double and triple bonds, free FAs and of oxygenated FAs), particularly with the development of modified normal phases. For example, silica gel can be impregnated with boric acid, which inhibits isomerization of mono- and diglycerides, or it can be treated with silver ions [argentation, for silver ion thin-layer chromatography (Ag-TLC)] used for resolution of unsaturated FAs. Gas chromatography (GC) and high-performance liquid chromatography (HPLC) are the most common techniques actually employed, because of their versatility (many parameters can be changed, e.g. stationary and mobile phases, detector) and to their capacity to be hyphenated (coupled with another measuring device). Particularly, the advent of the light-scattering detector has allowed greater reproducibility in the HPLC of lipids. Mass spectrometry (MS) is often coupled with GC. However, coupling MS with another MS (MS/MS or tandem MS) is useful for the determination of the structure of long-chain FAs with improved selectivity and sensitivity. Finally, nuclear magnetic resonance (NMR) is able to identify functional groups, even in mixtures, and is a valid aid for the elucidation of structures with double bonds (DBs) by interpretation of the coupling patterns.

Each analytical method relies on appropriate sample preparation (e.g. methylation for the GC analysis of FAs) and a critical approach to evaluate its usefulness.

1 INTRODUCTION

In plants, fats are synthesized from carbohydrates by the plant itself, while animal lipids come from two different sources: exogenous lipids ingested in food and endogenous lipids synthesized by animal tissues. In
animals, the former are nearly all triacylglycerols (TAGs), whereas the latter include a high proportion of polar lipids, chiefly phospholipids.\(^1\)

For numbering the three hydroxyl groups on the glycerol molecule, the convention originally proposed by Hirschmann\(^2\) is universally adopted. An \(sn-\) (stereo-specifically numbered) prefix is included in the names of all glycerols.\(^3\) A single molecular species is identified by listing the \(sn-1, \ sn-2\) and \(sn-3\) positions in order. An \(r\) prefix indicates that the middle FA in the abbreviation is attached at the \(sn-2\) position, while the remaining two acids are equally divided between the \(sn-1\) and \(sn-3\) positions, yielding a racemic mixture of two enantiomers. A \(\beta\) prefix indicates that the middle FA in the abbreviation is esterified at the \(\beta-\) or \(sn-2\) position. For example: \(sn-\text{OLLn}\) is \(sn-1\)-oleo-2-linoleo-3-linolenin; \(r\text{-OLLn}\) is equal proportions of \(sn-\text{OLLn}\) and \(sn-lnOL\); and \(\beta\text{-OLLn}\) is \(sn-\text{OLLn}\) plus \(sn-lnLO\) in any proportion.

In most species, saturated FAs tend to occupy mainly position \(sn-1\), though substantial amounts of oleic acid can also be found at that position. Unsaturated FAs and certain medium-chain FAs (C\(_{14}\)) are mainly concentrated at position \(sn-2\).

Long-chain FAs, such as stearic acid, are primarily located at position \(sn-1\), and unsaturated FAs (e.g. oleic acid and linoleic acid) at position \(sn-3\).

Very-long-chain polyunsaturated FAs occur mainly in the middle position in fish oils, with monoenoic acids concentrated in the outer positions.

The goal in the analysis of lipids is the complete resolution of the lipid classes and the molecular species for the identification and quantification of all components. Since no single analytical method is capable of identifying and quantifying all lipid species, analysis involves a multistep extraction, stepwise chromatographic resolution and sequential MS identification of lipid mixtures of progressively simpler compositions.\(^4\)

TLC can be used to separate different categories of lipids according to their functional groups, while Ag-TLC (with AgNO\(_3\)) separates TAGs according to the degree of unsaturation. Reversed-phase thin-layer chromatography (RPTLC) sorts according to carbon number (CN). GC assesses the degree of unsaturation of FAs and CN, while GC/MS is used for peak identification and quantification. HPLC is perhaps the preeminent method for separating TAGs.

### 1.1 Preparation of Samples

Sample preparation for GC, HPLC and MS must include cleaning for chemical and particulate contaminants to provide the component of interest in a solution, free from interfering matrix elements and in appropriate concentration for detection and quantification. This usually can be accomplished by sample purification and preliminary separation by TLC or HPLC.

Lipid samples are normally obtained by extraction with organic solvents but, recently, adsorption cartridges (solid-phase extraction) have been introduced to improve recoveries of the more polar components.

Neutral solvent methods of total lipid extraction result in low recoveries of acidic phospholipids, lysophospholipids and nonesterified FAs, while use of alkaline solvents may result in deacylated products depending upon the temperature and the time of exposure.\(^5\)

A lipid extract usually contains water and other non-lipid contaminants, which must be removed from the sample prior to derivatization, storage or chromatographic separation. A preliminary separation of lipid classes is also desirable. The small amounts of water in the solvent extract can be removed azeotropically during solvent evaporation, while small amounts of water with any water-soluble components can be removed by passing the wet organic solvent through a small column packed with anhydrous sodium sulfate.

In many cases, it is useful to effect a separation of the neutral and phospholipid fractions by some adsorption chromatographic technique using Florosil or silica gel as the adsorbent.\(^6\) Then, the polar and nonpolar lipid classes may be separated using commercial adsorption cartridges. In fact, TAGs and cholesteryl esters can be easily separated from the glycerophospholipids and sphingomyelins by sequential elution with mixtures of chloroform and methanol while complex acidic lipids and neutral phospholipids and ceramides can be resolved with methanol–water and chloroform–methanol mixtures, respectively.\(^7\)

A good separation of the lipid classes is obtained by adsorption TLC. Using a neutral solvent system for development, it is possible to retain the glycerophospholipids and sphingomyelins at the origin, while the neutral lipids are carried up the plate according to their \(R_F\) values.\(^8\) When using a polar solvent system, the neutral lipids are carried along together with the solvent front, while the phospholipids are resolved according to their polarity.

The strategy chosen for the analysis of specific lipids depends on the nature of the information needed and can frequently be achieved by adopting some established analytical routine. For example, FA analysis may require little more than a preparation of FA methyl esters from the total sample and a GC analysis. A more difficult problem may call for the analysis of the molecular species in a glycerolipid, which could require determination of the composition, molecular association and positional distribution of the FAs in a glycerolipid molecule.
2 THIN-LAYER CHROMATOGRAPHY

TLC is the simplest and still most widely employed technique in lipid analyses because it provides rapid and complete separations of most neutral and phospholipid classes.

Preliminary information on lipid composition can be easily obtained using TLC on silica gel layers with a solvent system such as hexane–diethyl ether–acetic acid (80:20:2 [by volume (v)]). Detection of all of the lipid classes can be made first under ultraviolet (UV) light (254 nm) or after spraying with the 1,2′-dichlorofluorescein and examining under UV light. Spraying with sulfuric acid–methanol (50:50) and subsequent heating gives a permanent record.

Generally, seven spot sections can be observed:

1. alkanes/alkenes/squalene/sterol ester/wax ester (Rf 98–94)
2. triglycerides (Rf 60; predominant)
3. free FAs (Rf 39)
4. sterols (Rf 19)
5. diglycerides (Rf 15–21)
6. monoglycerides (Rf 2)
7. phospholipids (Rf 0).

The TLC analysis is useful for a preliminary detection of the presence of compounds with conjugated double/triple bonds (detection under UV light), the presence of free FAs (Rf value comparison), and the presence of oxygenated FAs, unusual lipid classes or other unusual compounds.

Particular spray reagents permit the selective detection of keto, epoxy, hydroxy and cyclopropene groups. Even if the use of instrumental analytical methods is preferred, these TLC techniques may provide more complete information and are not hazardous.

If unusual TLC spots are detected, the lipid can be hydrolyzed, and the resulting nonsaponifiable matter and free-FA fractions can be separated and further analyzed.

2.1 Normal Phase Thin-layer Chromatography

A large variety of solvent systems and qualitative visualization reagents are available for normal-phase TLC, but usually the first approach is the TLC of a lipid sample in two or more solvent systems to examine its uniformity and fraction identity. The TLC separation can be increased further by the introduction of finer gel grades. When these are used in combination with smaller plates and thinner layers of adsorbent the technique is known as high-performance thin-layer chromatography (HPTLC). With this method it is possible to separate mixtures of nonpolar lipids, glycosphingolipids and phospholipids in one dimension. More than 20 different lipid subclasses are separated with three to four consecutive developing solvents. (This method was applied successfully to the analysis of glycosphingolipids from erythrocytes and other biological membranes in a simple identification of sphingolipidosis in patients.)

New strategies arise from the development of the TLC plate in two directions at a 90° angle with two different solvent systems. The solvent systems are chosen to enhance different properties of the lipid molecules and the plate is dried between developments. The development in each direction can be carried out with one or more solvent systems and chromatographic conditions, thus giving rise to a large number of variations. The second TLC separation can also be performed following isolation of the components resolved in the first TLC separation.

2.2 Modified Normal Phase

TLC may be used after impregnation of the silica gel with special additives, e.g. boric acid or AgNO3.

2.2.1 Modification with Boric Acid

Silica gel impregnated with boric acid is used to prevent or minimize the isomerization of mono- and diacylglycerols during chromatographic separation. The borate is incorporated into the silica gel at 5–10% and the plates are spread, dried, activated and developed in the usual manner. The boric acid forms complexes with vicinal hydroxyl groups and thus blocks the transfer of fatty acyl chains from one position to another.

2.2.2 Argentation

Argentation TLC (Ag-TLC) is extensively utilized for analytical and semipreparative resolution of methyl and glycerol esters of saturated and unsaturated FAs. The incorporation of 5–20% AgNO3 into the silica gel permits effective complexing of the FAs with silver ions, which retard the migration of the polyunsaturated FAs. The separation is based essentially on the number of DBs per molecule and separate bands are obtained for compounds with 0–6 DBs per molecule.

2.3 Reversed Phase

RPTLC systems have been developed using RP-18, RP-8 or CN plates. Resolution of fatty acid methyl esters (FAMES) by TLC is often complicated by co-migration of certain acyl isomers in heterogeneous mixtures: An RPTLC method that employs 10% [weight/volume (w/v)] AgNO3 in a mobile phase containing acetonitrile–1,4-dioxane–acetic acid (80:20:1 v/v)
allows one-dimensional resolution of a wide range of acyl methyl esters. This innovation enables improved separation of saturated FAME ranging from \( \text{C}_{12} \) through \( \text{C}_{22} \) from unsaturated FAME by TLC.\(^{(20)} \)

### 3 GAS CHROMATOGRAPHY

GC can be considered one of the most valuable and most efficient methods of resolution and quantification of lipids. The development of flexible fused quartz capillary columns has made capillary GC the method of choice and is gradually phasing out packed GC columns from research laboratories. Except for electron capture, the flame ionization detector (FID) has replaced all others for lipid GC.

Quantification in GC (and also in HPLC) is based on the principle that the masses of each of the separate constituents in the mixture are proportional to the area under each peak.

The retention time is reflected by the distance on the chromatogram between the air peak and the position of the band peak. Working with an \( \text{H}_2 \) flame detector, the air outflow is not detectable; in that case elution of the solvent can be taken as a starting point.

#### 3.1 Columns

Packed or capillary columns may be employed. Packed columns range from 1.5 to 3 m in length, with an internal diameter of 2–4 mm and diatomaceous earth or other support and a narrow range of particle sizes (between 125 and 200 \( \mu \)m). The stationary phase is normally a polyester-type polar liquid (e.g. diethylene glycol succinate) or others such as cyanosilicone, methyl silicone, etc.\(^{(21-23)} \)

The working temperature ranges from 175 to 200 °C, depending upon the column type.

Capillary columns may be made of glass or fused silica gel. Internal diameter ranges from 0.2 to 0.8 mm, and column length from 25 to 100 m depending upon the type of acid to be separated. The preferred stationary phase is of polyethylene glycol chemically bonded. The bonded phase thickness should be from 0.1 to 0.2 \( \mu \)m.

#### 3.2 Detectors

The quantification of the chromatograms is essentially a function of the detector and is easy with detectors that give a reproducible mass or molar response. It is also helpful to have a sensitive detector response that is linear over the working range for all analytes in the sample.

Since natural glycerolipids usually do not contain chromophores, they are best detected by the universal detection systems such as FID and total ion current in MS, or light scattering for HPLC.

The FID responds essentially to the carbon mass in the solute. It is sensitive and possesses a wide dynamic range. It is not affected by temperature programming in GC or solvent gradients in HPLC and requires minimal calibration except for components of very-high molecular mass in GC.

#### 3.3 Quantification

For quantification, the peak area of each component is reported as a percentage of the total area of all peaks. These results reflect the relative composition of a multicomponent sample, provided all the components are eluted, separately detected and give the same detector response per weight or mole unit. When the detector response is not equivalent, the area percentage of a component is multiplied by a response factor, which must be determined, to reflect the weight or mole percentage of the component reaching the detector.\(^{(24,25)} \)

##### 3.3.1 Use of an Internal Standard

Use of an internal standard is the most satisfactory method for the quantification of neutral lipids and FAME.\(^{(26)} \) A sample of an appropriate standard (e.g. \( \text{C}_{17} \) or \( \text{C}_{23} \) methyl esters for FAs and \( \text{C}_{30} \) TAG for neutral lipids) equivalent to 10–20% of total peak area is added to the sample before introduction into the chromatograph. After chromatography, the peak areas for the analyte and the internal standard are measured and peak area ratios are determined. The amount of each unknown is calculated in relation to the known concentration of the standard. Using an internal standard, the errors arising at each step are self-compensating, because both standard and unknown are affected proportionally.

##### 3.3.2 Use of External Standard

In external standardization, response curves are established for each unknown by injecting into the chromatograph progressively larger amounts of reference compounds and recording the quantitative response.\(^{(27,28)} \) The peak area recorded for the unknown is then compared with the corresponding point on the standard curve and the concentration of the unknown read off from the graph. The standards are prepared in the same solvent as the unknowns and the standard response must be confirmed before and after the analysis of the unknowns.
4 HIGH-PERFORMANCE LIQUID CHROMATOGRAPHY

Neutral lipid classes and molecular species can be successfully separated by HPLC, even if many problems are associated with the detection of the nonchromogenic lipids in the column effluent. These problems have been largely overcome by the use of the universal light scattering, hydrogen FID (hydrogen FID) and MS detectors.

4.1 Detectors

The development of the light scattering detector has revolutionized HPLC of lipids. Detection is achieved by nebulizing the column effluent in a stream of tepid gas. Although the response is nonlinear and the dynamic range more limited than that of the FID, the light or laser light scattering detector responds to all glycerolipids in a reproducible manner.

Both UV absorbing and fluorescent derivatives yield essentially molar responses, which lend readily to quantification of all molecular species over a wide concentration range.

Furthermore, wavelength ratios and absorption spectra provide useful, although not definitive, information about the identity or purity of the peak.

The refractive index and short-wave UV detection systems employed in early HPLC of glycerolipids are best suited for qualitative work, although important quantitative applications have been reported. These detectors require extensive calibration and are subject to serious solvent restrictions.

HPLC with a refractive index detector can achieve quantitative analysis of synthetic mixtures of saturated TAGs (with FAs from caprylic to stearic), using an eluent of propionitrile and butyronitrile (80:20 v/v). Furthermore, normal-phase HPLC is well suited for the preparative resolution of the diacyl-, alkylacyl- and alkenyacylglycerols as the acetates, trimethylsilyl and tertbutyldimethylsilyl ethers or benzoyle, dimitrobenzoyl, naphthyl, anthroyl and pyrenyl derivatives. The elutions are performed with solvents of low polarity and the elution order of the three (or any two) is the same: alkenyacyl > alkylacyl > diacyl.

1,3- and 1,2-Diacylglycerols can be resolved by normal-phase HPLC, but 1,3-isomers of low molecular weight interfere with 1,2-isomers of high molecular weight. The 1(3)-isomers were eluted ahead of the 2-isomers of monoacylglycerols when run in the undervatized form. Normal-phase HPLC has also been used for the isolation of mono- and digalactodiacylglycerols.

4.2 Columns

4.2.1 Normal Phase

Normal-phase HPLC is used mainly for lipid class separations, since molecular species have long equilibration times and show poor resolution. Thus, TAGs and monoand diacylglycerols are readily resolved from each other and from cholesteryl esters and glycerophospholipids. Like the TAGs, the long-chain diracylglycerols can be readily recovered as a lipid class from normal-phase HPLC, with very limited fractionation. The corresponding X-1,3- and X-1,2-diracylglycerols are resolved, with the X-1,3-isomers emerging ahead of the X-1,2-isomers, again as established for normal-phase TLC. Normal-phase HPLC also allows the separation of TAGs containing common and hydroxy FAs.

Furthermore, normal-phase HPLC is well suited for the preparative resolution of the diacyl-, alkylacyl- and alkenyacylglycerols as the acetates, trimethylsilyl and tertbutyldimethylsilyl ethers or benzoyle, dimitrobenzoyl, naphthyl, anthroyl and pyrenyl derivatives. The elutions are performed with solvents of low polarity and the elution order of the three (or any two) is the same: alkenyacyl > alkylacyl > diacyl.

1,3- and 1,2-Diacylglycerols can be resolved by normal-phase HPLC, but 1,3-isomers of low molecular weight interfere with 1,2-isomers of high molecular weight. The 1(3)-isomers were eluted ahead of the 2-isomers of monoacylglycerols when run in the undervatized form. Normal-phase HPLC has also been used for the isolation of mono- and digalactodiacylglycerols.
16:0, 18:1, 16:1, 18:2 and 18:3. The peaks of 1- and 2-monoacylglycerols with the same acyl group show complete overlapping.

The major soybean phospholipids can be separated on β-cyclodextrin-bonded silica using isocratic elution with hexane, isopropanol, ethanol or water–tetramethylammonium phosphate as the mobile phase, and UV detection. The presence of tetramethylammonium phosphate in the mobile phases is critical for good resolution.

4.2.3 Reversed Phase

RPHPLC with short wavelength UV detection (210 nm) can be used for the analysis of TAGs containing highly unsaturated FAs, including α- and γ-linolenic acids. This, however, requires increased detector sensitivity, which is achieved by employing a thermostat to stabilize the temperature of the entire HPLC system.

A typical reversed-phase column consists of 5–10µm alkane-bonded silica gel (C18, C8, etc.). Solvent temperature programming has been shown to provide advantages for resolution and peak recovery as well as for expanding the range of solvent types or combinations available for separation of those compounds that are difficult to dissolve in the semi-aqueous solvents.

Critical pairs, which result from the approximate equivalence of one DB to a chain shortened by two methylene units, are effectively separated with acetone–acetonitrile (63.6:36.4 v/v) as an isocratic mobile phase. Other solvent systems are also capable of resolving critical pairs and triplets of TAGs. An acetone–acetonitrile system has been adapted to the HPLC resolution of butterfat TAGs, but the greatest improvement results from simply decreasing the sample load.

Excellent resolution of fish oil TAGs on RPHPLC is obtained using a gradient of 10–90% isopropanol in acetonitrile.

The mobile phase for RPHPLC of polar lipids consists of an aqueous component and an organic modifier (5–40% for most applications), with a third component occasionally added as an ion-pairing reagent. The molecular species of intact glycerophospholipids are resolved using methanol–water–acetonitrile along with choline chloride or phosphate salts.

4.2.4 Chiral Phase

Although enantiomeric TAGs cannot be resolved, their random deacylation products can be separated by chiral-phase HPLC following conversion into DNPU derivatives, while separations of diracglycerols can be carried out on N-(S)-2-(4-chlorophenyl)isovaleroyl-D-phenylglycine chemically bonded to γ-aminopropyl silanized silica.

The sn-1,2-enantiomers are eluted well ahead of the sn-2,3-enantiomers of the monoacid diacylglycerols. Improved separation of enantiomeric diacylglycerols can be obtained with N-(R)-1-(1-naphthyl)ethylaminocarbonyl-(S)-valine liquid phase, which could be employed for the resolution of mixtures of homologous diacylglycerols.

Effective resolution of the enantiomers of unsaturated diacylglycerols derived from natural fats and oils by Grignard degradation can be provided by the (R)-1-(1-naphthyl)ethylamine liquid phase. The molecular species of the resolved diacylglycerols are then identified by on-line MS.

Excellent resolution of the enantiomeric monoacylglycerols and monoalkylglycerols can be also obtained using amide-urea type chiral phases.

A new chemical method suitable for the stereospecific analysis of marine biogenic lipid triacyl-sn-glycerols was reported by Ando et al. Triacyl-sn-glycerols are partially hydrolized with ethyl magnesium bromide and 1-monoacylglycerol products are resolved into sn-1 and sn-3 monoacylglycerol fractions by HPLC on a chiral column (50 cm x 4 mm internal diameter), packed with 5µm particles of N-(R)-1-(α-naphthyl)ethyl-aminocarbonyl-(S)-valine chemically bonded to γ-aminopropyl silanized silica (Sumichiral OA-4100, Sumitomo Chemical Co., Osaka), using a mixture of hexane–1,2-dichloroethane–ethanol (40:12:3 v/v/v) as mobile phase at a constant flow rate of 0.5 ml min⁻¹.

4.3 Preliminary Resolution with Thin-layer Chromatography

Although lipids can be resolved into individual classes and molecular species by HPLC alone when the mixture contains total neutral lipids, it is frequently advantageous to effect a preliminary resolution of lipid classes by TLC to avoid potential overlaps among different homologous series. Thus, the individual phospholipid classes resolved by normal-phase TLC during the initial isolation and purification can be subjected to RPHPLC either in the intact form or following dephosphorylation and conversion into UV-absorbing derivatives.

Combining Ag-TLC with RPHPLC, it is possible to increase fractionation of short-chain TAGs from butterfat. Using Ag-TLC with DNPU derivatives of 1,2(2,3)-diacylglycerols combined with chiral-phase HPLC permits the separation of the molecular species of diacylglycerols derived by Grignard degradation. The sn-1,2(2,3)-diacylglycerols were resolved from X-1,3-diacylglycerols by borate TLC.
4.4 Subsequent Characterization with Gas Chromatography

HPLC/GC can be also employed for identification of the components resolved by normal, silver ion, reversed-phase or chiral-phase HPLC. Normal-phase HPLC may be employed instead of TLC for the isolation of neutral and polar lipid classes for subsequent GC examination on polar or nonpolar columns following appropriate derivatization.(13)

The diacyl-, alkylacyl- and alkenylacylglycerol subclasses have been completely resolved by combining normal-phase HPLC with polar capillary GC of the trimethylsilyl ethers.(66) Both reversed-phase(67) and silver ion(68,69) HPLC can provide small groups of molecular species of TAGs for improved subsequent GC analysis as intact molecules on polarizable capillary columns. In more conventional approaches, fractions from silver ion HPLC are analyzed by GC for FA composition.(69)

Chiral-phase HPLC provides effective resolution of the enantiomeric mono- and diacylglycerols but fails to resolve completely the component molecular species, which must be identified by other methods, including GC.

5 MASS SPECTROMETRY/MASS SPECTROMETRY

MS/MS is used for the structural analysis of long-chain carboxylic acids. It provides additional information and can also improve selectivity and sensitivity. It is achieved by arranging two or more mass spectrometers in a series. Specificity and sensitivity is further improved by coupling MS/MS to capillary GC and HPLC.

MS/MS is MS of a specific ion selected from the initial mass spectrum. The selected parent ion is allowed to enter a field-free reaction region, where it may undergo unimolecular or collision-induced dissociation (CID). The resulting fragments (daughter ions) are analyzed by a second mass spectrometer, which provides the MS/MS spectrum (MS/CID/MS). Generally the intermediate field-free region is used as a collision chamber where the internal energy of the parent ion is increased through collisions with some target gas. This increased internal energy induces the ion to fragment into daughter ions, which are then analyzed in the second mass analyzer. The daughter ions are characteristic of the structure of the parent ion and the MS/MS allows the determination of that structure.(70–73)

The maximum amount of the original kinetic energy of the parent ion that can be transformed into the internal energy needed for CID is regulated by the need to conserve the total momentum (Equation 1):

\[ E_{\text{max}} = \frac{M_2}{M_1 + M_2} E_{\text{ion}} \]

where \( E_{\text{max}} \) is the maximum amount of internal energy acquired in the collision; \( E_{\text{ion}} \) is the original kinetic energy of the parent ion; \( M_2 \) is the mass of the target atom or molecule; and \( M_1 \) is the mass of the parent ion.

Although the first mass spectrometer separates the mixture from the gas or the liquid chromatograph and the second determines the mass spectra of the molecular ion, the method differs from both GC/MS and HPLC/MS, which are based on chemical separation. In MS/MS, the initial separation is based on physical properties. This approach allows assessment of neutral fragment loss and parent ion scans, which have no counterpart in GC/MS or HPLC/MS. In addition, in MS/MS, the first mass spectrometer serves to filter out the background and improves the signal-to-noise ratio.

5.1 Methods of Ionization

The soft ionization MS techniques, such as fast atom bombardment, field desorption, thermospray and electrospray, have the ability to ionize lipid molecules without causing extensive fragmentation. This generally leads to mass spectra characterized by molecular adduct ions. Ion-spray, which can be used with flow rates compatible with HPLC, is similar to electrospray except that the initial nebulization process is assisted by pneumatic or ultrasonic means. Electrospray favours multiply charged ions for proteins, but FAs and their esters usually acquire only one charge per molecule.

The desorption–ionization methods have been most often employed in the past to generate the parent ions of large polar organic molecules. More recently, thermospray and electrospray have also been used for this purpose because they may be coupled to HPLC by appropriate interfacing. The most common method used to obtain fragmentation of the molecular ionic species produced by a “soft ionization” process is CID.

Electrospray has a very unique property that distinguishes it from other soft ionization techniques. It can be used to produce CID spectra of singly charged species with greater sensitivity than can be achieved with triple quadrupole mass spectrometer (QqQ) electrospray MS/MS systems.

When analytes are present in the sprayed solution, molecular adducts, typically protonated parent ions \([M + H]^+\), are formed and guided into the reaction region of the mass spectrometer between the exit of
the glass capillary and the first skimmer. If a low voltage of 50–120 V is applied to the capillary exit, the molecular ionic species remain intact and the molecular mass of the analyte is obtained. However, if higher voltages are applied to the capillary exit, extensive and reproducible fragmentation of the molecular adduct ion can be achieved.

The best results in terms of sensitivity, specificity and reproducibility are obtained by using HPLC as a separation device combined with the electrospray CID/MS method instead of relying on the selection of specific masses from mixtures and using the first Q of a QqQ system for the separation.

6 NUCLEAR MAGNETIC RESONANCE SPECTROSCOPY

In the past, NMR spectroscopy was mainly a tool for the analysis of pure compounds. As a consequence of the now widely available high-resolution spectrometers, the improvement of computer power and the introduction of new pulse sequences, the technique can also be applied with great success to lipids.

6.1 Proton Spectroscopy

The detection of a number of functional groups in seed oils, such as allenes, conjugated DBs, conjugated double–triple bonds, cyclopropane and cyclopropene rings, cyclopentene, epoxy, hydroxy, and terminal vinyl groups, is possible by their characteristic \(^1\)H NMR signals.\(^{74–81}\) The methylene groups adjacent to a keto group show shift values similar to those adjacent to the carboxyl group when located remote from the carboxyl or other functional groups. However, in some special cases, the presence of a keto group can be indicated by its \(^1\)H NMR spectrum as shown, e.g. for 4-keto-\(\alpha\)-eleostearic acid.

By an appropriate interpretation of the coupling patterns and consideration of the integral values of the signals, the configuration of the DBs in conjugated systems can be elucidated even in mixtures.\(^{82}\) Furthermore, it is possible to distinguish FAs that contain a DB at the n-3 terminal from other unsaturated FA isomers by means of their terminal methyl signals.\(^{83,84}\) For example, in the case of a seed oil that contained two n-3 acids (linolenic and \(\alpha\)-parinaric acid (18:4) (9c, 11t, 13t, 15c)), even the separation of their terminal methyl and allylic methylene \(^1\)H NMR signals (Figure 1) could be observed in the oil mixture.\(^{85}\)

By integration of distinct \(^1\)H NMR signals, a quantification of unusual FAs in lipid mixtures can be effected in an easy and nondestructive way, as was shown for cyclopropene,\(^{79}\) n-3 FAs,\(^{83}\) and epoxy FAs.\(^{86}\)

6.2 Spectroscopy with Carbon-13

Because of the naturally low content of the \(^13\)C isotope (\(^{12}\)C/\(^{13}\)C NMR = 98.9/1.1), \(^{13}\)C NMR spectroscopy is an

![Figure 1](image-url) Proton NMR spectrum of a Euphorbiaceae seed oil (500 MHz). Signal groups (ppm) at chemical shift 8 0.88 (CH\(_3\), all FAs); 0.968 (CH\(_3\), linolenic acid); 1.0 (CH\(_2\), parinaric acid); 1.28 (bulk CH\(_2\)); 1.58 (CH\(_2\)--CH\(_2\)--COOR, all FA); 2.05 (allylic CH\(_2\)); 2.2 (allylic CH\(_2\), parinaric acid); 2.3 (–CH\(_2\)--COOR); 2.8 (double allylic CH\(_2\)); 4.1–4.3 (glycerol CH\(_2\)); 5.25 (glycerol CH); 5.35 (alkenic CH); 5.43–6.5 (conjugated alkenic CH, parinaric acid). (Reproduced by permission of AOCS Press from Spitzer et al.\(^{85}\))
Insensitive method for routine analysis. The detection limit for each FA is 2–5%, depending on its structure and measuring parameters.

When a spectrum is recorded routinely in the broad-band decoupled mode, the signals of the functional groups of FA are weak in comparison to those of the methyl, methylene and methine signals (nuclear Overhauser effect) and may be overlooked.

The chemical shift and the intensity of the $^{13}$C NMR signals provide structural information on the individual FAs and lipid classes, and even in some cases the distribution of the different acyl groups on the glycerol backbone and the position of the unsaturated centers and functional groups in the acyl group.\(^{87}\)

### 6.3 Two-dimensional Spectroscopy

The measurement of two-dimensional NMR spectra can provide useful structural information. The $^1$H–$^1$H homonuclear and $^1$H–$^{13}$C heteronuclear correlation NMR spectroscopy techniques enable the identification of the configuration of the conjugated triene system of α-olestearic acid in cherry oil\(^{82}\) and the configuration and localization in the FA chain of the conjugated tetraene system of α-parinaric acid in a Euphorbiaceae seed oil.\(^{85}\)

With high-field $^1$H NMR (600 MHz), it is possible to effect the simultaneous detection of minor compounds of olive oil, such as aldehydes, diacylglycerols, linolenic acid, water, acetic acid, phenols and sterols by using two-dimensional totally correlated spectroscopy and nuclear Overhauser effect spectroscopy.\(^{88}\)

### 7 ANALYSIS OF FATTY ACIDS

#### 7.1 Gas Chromatographic Analysis

FAs are commonly analyzed by GC of their FAMEs, although sometimes it is also possible to effect the GC separation of underivatized FAs.\(^{89}\) The total gas chromatographic analysis of FAMEs has several steps: FA esterification and the injection, separation, identification and quantification of the derived FAMEs.

##### 7.1.1 Preparation of Fatty Acid Methyl Esters

To be analyzed by GC, the FAs of lipids have to be split off and converted into derivatives with lower boiling points, such as esters of alcohols. The FAs are removed from the glycerol, sterol or alcohol by saponification with sodium hydroxide or potassium hydroxide, then methylated with either boron trifluoride–methanol reagent\(^{90}\) or with methanolic mineral acids.\(^{91}\)

Saponification–esterification procedure requires very long reaction times. Direct transesterification of lipids (“alcoholysis”) proceeds more rapidly than saponification, with hydrolysis and esterification taking place in one step, and requiring only one reagent.

Some problems are associated with ester preparation by transesterification, for example:

- incomplete conversion of lipids into FAMEs
- changes in the original FA composition during transesterification
- formation of artefacts that can be wrongly identified as FAs or overlap with FAME peaks in the GC analysis
- contamination of the GC column with traces of the esterification reagent
- incomplete extraction of FAMEs after transesterification
- losses of highly volatile short-chain FAMEs.

The reagents used for methylation are based mainly on methanol. Because nonpolar lipids (triglycerides, cholesterol esters) are not soluble in the transesterification reagents and cannot react in a short time, solvents such as benzene, toluene, chloroform or tetrahydrofuran have to be added to dissolve these lipids.\(^{92-93}\)

Normally, after transesterification, FAMEs have to be extracted with alkanes such as n-pentane, n-hexane or isooctane. Water or salt solutions are added to increase recovery of FAMEs.

Because methyl esters of short-chain FAs, such as those present in dairy products, are highly volatile and are partially soluble in water, quantitative recovery is very difficult. For samples that contain short-chain FAs, the preparation of butyl esters,\(^{94}\) which have higher boiling points and are less water soluble than methyl esters, is recommended.\(^{95}\)

#### 7.1.2 Acid-catalyzed Transesterification

Common reagents used for acid-catalyzed transesterification are methanolic hydrochloric acid, methanolic sulfuric acid, and boron trifluoride in methanol. All are suitable for lipid transesterification and also for free FA methylation.

However, neither reactions catalyzed by acid nor those using acid boron-trifluoride proceed at ambient temperature; both types of reaction require heating. Boron trifluoride–methanol reagent (12–14% w/v) is most often used for transesterification of all types of lipid.\(^{96}\) The reaction at 100°C requires 30 min for phosphoglycerides and triacylglycerides and 90 min for sphingomyelin. (A small sample of the lipid extract (dissolved in chloroform) is placed in a screw-capped tube (Teflon cap liner); 0.5 to 1 ml boron trifluoride–methanol
reagent (140 g·L\(^{-1}\), containing an adequate amount of butylated hydroxytoluene as antioxidant) is added; the tube is then closed and heated at 90°C for 2 h.) After the transesterification has been completed, FAMEs are extracted twice by adding \(n\)-hexane and water.

Anhydrous methanol containing hydrochloric or sulfuric acids has been used for lipid esterification under very different conditions. Complete transesterification with 5% methanolic hydrochloric acid can be carried out by heating the sample in the reagent under reflux for about 2 h. The reaction can also be carried out at 50°C overnight. A solution of 1–2% (v/v) concentrated sulfuric acid in methanol can be used in the same way for the transesterification of lipid samples.

7.1.3 Base-catalyzed Transesterification

Reagents usually used for base-catalyzed transesterification of lipids are sodium methoxide and potassium hydroxide in methanol.

Transesterification with sodium methoxide proceeds at ambient temperature very rapidly,\(^{(95)}\) and the risk of decomposition of polyunsaturated FA is lower. However, it does not esterify free FAs and it does not transesterify sphingolipids. It is possible to use a combined procedure for the conversion of free and glyceride-bound FAs. In the first step, sodium methoxide is used for the transesterification of glycerol-bound FAs, and in the second step methanolic hydrochloric acid is used for the esterification of any free FAs.\(^{(97)}\)

Another reagent used for the transesterification of lipids is potassium hydroxide in methanol, but this has the disadvantage of a potential risk of saponification during transesterification.

7.1.4 Sample Injection

In high-resolution GC, sample injection is the most critical step with respect to achieving high accuracy and precision.

7.1.4.1 Split Injection

With the split injection, the sample is introduced into a hot injector chamber or injection port. Splitting of the carrier gas (normally in a range between 1 : 10 and 1 : 200) has the advantage that samples with relatively large FAME concentrations can be injected without the risk of overloading the stationary phase, causing degradation of column performance. Injector temperatures for FAME injection are 250–300°C or even below 250°C.

The main problem of the classical split injection technique in FAME analysis is discrimination between high-boiling and low-boiling compounds in the sample, owing to changes in the splitting ratio caused by pressure waves, selective evaporation in the syringe needle and incomplete evaporation.\(^{(98)}\) Sample discrimination can be avoided by preventing sample discrimination in the syringe needle, vaporizing the sample rapidly and mixing the vaporized sample thoroughly with the carrier gas. This can be achieved by high-speed injection, small sample volumes, low sample concentrations, high injector temperatures (375°C), good injector insert designs and frequent cleaning of the insert.

7.1.4.2 On-column Injection

The problems associated with split injection can be overcome by the use of cold sample injection: on-column injection or programmed-temperature vaporizing injection.

In the on-column technique, the sample is directly introduced into the cool section of the column and no prior vaporization in a hot injector chamber is required. As no sample splitting is performed and as no evaporation of the sample occurs in the syringe needle, sample discrimination can be completely avoided. Consequently, samples with a wide range of component volatilities can be determined with high accuracy and precision.\(^{(99,100)}\)

In programmed-temperature vaporization, the sample is introduced into a cold vaporizing chamber that is packed with deactivated glass or quartz wool for homogeneous mixing of sample and carrier gas. After withdrawal of the syringe needle and after evaporation of the solvent, the vaporizing chamber is very quickly heated to 250–350°C for evaporation of the higher-boiling compounds. This technique can be used in three different operation modes: cold split injection, cold splitless injection and solvent elimination injection.

Splitless injection, in general, is useful for the analysis of very dilute solutions while the solvent elimination technique allows the injection of large sample volumes (up to 250 μL). This technique is critical for the analysis of FAs containing less than 16 carbon atoms because these FAs can be lost together with the solvent through the split exit.\(^{(101,102)}\)

7.1.5 Separation of Fatty Acid Methyl Esters

The separation of FAMEs can be carried out routinely by means of high-resolution modern capillary columns (with a length of 50 m and more and 10\(^5\) or more theoretical plates). These are suitable for a wide range of chain lengths (CLs). Packed columns are still acceptable for the analysis of simple FAME mixtures such as vegetable oils, which contain no FA with more than 18 carbon atoms.

7.1.5.1 Stationary phases

Separation of FAMEs is carried out with three different types of capillary column: nonpolar, polar and very polar. The polarity of the stationary phase influences retention times of FAMEs, especially those of polyunsaturated types. The column should be chosen according to the sample to be analyzed. In general, the resolution capability for
FAMEs, especially for unsaturated types, is highest in columns with very polar phases.

Complete analyses of all common FAs may be obtained with FAME using polar capillary columns and FID.

The polar capillary columns (consisting of bis-cyanopropylsiloxane) also yield effective separation of all CL and double-bond number homologs, including most positional double-bond isomers; however, only certain cis and trans positional isomers are resolved. Other cis and trans isomers and methyl and hydroxyl substitution isomers are not resolved and longer columns or special liquid phases (e.g. 60–100 m SP-2340 or SP-2560) have been chosen for their separation.\(^{(103)}\)

In polar capillary GC of the TAG esters of long-chain FAs, the choice of the column length is critical because the recoveries decrease greatly with increasing column length, although the resolution increases.\(^{(104)}\) The longer columns, however, require higher operating temperatures (e.g. 280–300 °C).

The most important very polar stationary phases are composed of 100% cyanopropylsilicone oil (SP-2340, OV-275), 100% cyanopropylsilicone (CP\(^{m+}\)-Sil 88) or biscyanopropyl–dimethylsiloxane (SP-2330) (68:32 v/v).

The main advantage of polar phases compared with nonpolar phases is their high resolution of unsaturated FAMEs. If a critical pair of FAMEs, such as 20:3n-3 and 20:4n-6, co-elute on a specific phase, resolution can be achieved in most cases by use of a more polar phase.

Given a constant CL, every additional DB increases the retention time. At a constant number of DBs, FAMEs in which the last DB is located farther away from the \(w\)-end elute before those in which the last DB is located closer to the \(w\)-end. In the FAs with 18 carbon atoms, the elution order is: 18:0, 18:1 (n-9), 18:1 (n-7), 18:2 (n-6), 18:3 (n-6), 18:3 (n-3), 18:4 (n-3).

Geometrical double-bond isomers can be resolved to a certain extent on very polar capillary columns of the cyanosilicone type.

The analysis of trans FAs in foods (occurring mainly in partially hydrogenated oils and fats and in ruminant fats) is becoming of considerable importance because of the implications of these acids for human health.\(^{(105)}\) On very polar columns, the C\(_{18}\) monoethylenic trans FAs elute before the corresponding monoethylenic cis FAs, with some overlap.\(^{(105)}\)

All geometrical isomers of linolenic acid methyl ester on a CP\(^{m+}\)-Sil 88 coated capillary column can be separated under isothermal conditions within 45 min. As in the monoethylenic FAMEs, the inclusion of cis DBs increased retention times compared with corresponding positions of trans DBs. The elution order of the geometrical isomers of linolenic acid methyl ester is: \(\text{ttt} < \text{ctt} < \text{ttc} < \text{ctc} < \text{etc} < \text{tcc} < \text{ccc}\), where \(t\) indicates trans and \(c\) indicates cis.

Equivalent chain length (ECL) values ranged between 19.45 and 19.89.\(^{(106)}\)

The most important stationary phases of intermediate polarity are polyethylene glycol (DB-Wax, SUPELCOWAX-10, Carbowax 20M),acidified polyethylene glycol (FFAP), dimethyl–cyanoethylpolysiloxane (DB-1701) (86:14 v/v) and cyanopropyl–phenyl–methyl (25:25:50 v/v) methylsilicone polymers (OV-225, DB-225, SP-2300). The main nonpolar stationary phases are based on dimethylsilicones (SPB-1, SPB-5) such as dimethyl–diphenylpolysiloxane (95:5 v/v) (DB-5, SPB-5, CP\((m+)+\)-Sil 8CB) or 100% dimethylpolysiloxane (DB-1, Rt-1, SPB-1, SP-2100, OV-1, OV-101, CP\((m+)+\)-Sil 5CB).\(^{(107)}\)

Figure 2 shows the separation of FAMEs from a human milk sample on a CP\((m+)+\)-Sil-5 cross-linked methylsilicone-coated column.

The nonpolar columns allow also a partial resolution of the saturated and unsaturated FAME, with the unsaturated species emerging slightly earlier than the corresponding saturated species. The nonpolar liquid phases vary in chemical structure and in their interaction with the FAs giving slight differences in relative migration rates, which, along with the film thickness and column length, can be exploited to minimize peak overlap. Generally lipid chemists favor the polar liquid phases for FAME.

The operating temperature constitutes an important practical aspect. Increases in column temperature increase the speed of the analysis but may decrease the peak resolution (the column life-time is reduced and the properties of the liquid phase may change).

Different liquid phases have different maximum operating temperatures. During the chromatography of TAGs, column temperatures exceeding 350 °C are necessary and only a few liquid phases are suitable for this purpose.

Other critical aspects of practical GC concern for TAGs include the method of sample introduction. In usual GC operations, the sample must be evaporated at a temperature that is higher than the column. High-temperature resolution of glyceryl and steryl esters is best performed by admitting the sample directly to the column at its starting temperature, which may be advantageously combined with programmed temperature vaporization.

Using capillary columns, it has been proven that the highest recoveries of components are obtained following on-column injection at or below the column temperature. This is performed using flexible quartz needles with wide bore capillaries,\(^{(108)}\) or a special movable (“pop-up”) on-column injection apparatus\(^{(109)}\) in which the sample is introduced while the front end of the column is outside the oven. Following injection of the sample, the column
Figure 2  Separation of FAMEs from a human milk sample from Curacao on a CP\textsuperscript{2}®-Sil-5 cross-linked methylsilicone-coated capillary column (50 m × 0.20 mm internal diameter). Chromatographic conditions: split injection (split ratio 1 : 20); oven temperature program 60 °C, 4 °C min\textsuperscript{-1} to 200 °C, 50 °C min\textsuperscript{-1} to 285 °C, 285 °C for 15 min; carrier gas helium (0.52 ml min\textsuperscript{-1}). Peaks: 1, 5 : 0; 2, 6 : 0; 3, 7 : 0; 4, 8 : 0; 5, 9 : 0; 6, 10 : 0; 7, 11 : 0; 8, BHT; 9, 12 : 0; 10, 13 : 0; 11, 14 : 1; 12, 14 : 0; 13, 15 : 0; 14, 16 : 1 (n-7); 15, 16 : 0; 16, 17 : 0; 17, 18 : 3 (n-6); 18, 18 : 2 (n-6) + 18 : 3 (n-3); 19, 18 : 1 (n-9); 20, 18 : 1 (n-7); 21, 18 : 0; 22, 20 : 4 (n-6); 23, 20 : 5 (n-3); 23a, 20 : 3 (n-9); 24, 20 : 3 (n-6); 25, 20 : 2 (n-6); 26, 20 : 1 (n-9); 27, 20 : 0; 28, 22 : 5 (n-6); 29, 22 : 6 (n-3); 30, 22 : 4 (n-6); 31, 22 : 5 (n-3); 32, 22 : 0; 33, 24 : 1 (n-9); 34, 24 : 0; 35, 5β-cholestan-3α-ol; 36, cholesterol. (Reprinted from G. van der Steege et al., ‘Simultaneous Quantification of Total Medium- and Long-chain Fatty Acids in Human Milk by Capillary Gas Chromatography with Split Injection’, J. Chromatogr. B, 415, 1–11, Copyright (1987), with permission from Elsevier Science.)

is returned to the oven held at the desired starting temperature. Capillary columns with split or splitless injection systems, which depend on evaporation with the sample, are not well suited for injection of solutions of compounds with a wide range of molecular masses. Such samples are evaporated and split at different ratios, usually resulting in poor recoveries of the components of higher molecular mass. No difficulties were encountered with determination of plasma total lipid profiles if on-column injection was used.

High-temperature GC on nonpolar columns has been extensively applied in the determination of total lipid profiles, and CN of diacylglycerols and TAGs. The original separations obtained on short packed nonpolar columns have been compared favorably with the separations obtained on capillary columns, including columns made with bonded nonpolar liquid phases. The use of hydrogen as carrier gas and of capillary columns of minimum length have greatly improved the recovery and shortened the retention times of the compounds of higher molecular mass. The nonpolar liquid phases still require derivatization of any polar functional groups. Trimethylsilyl and terbutyldimethylsilyl derivatives are especially useful; they increase the volatility of the molecules and allow their recovery at lower temperatures and slightly shorter retention times than achieved with the corresponding acetates.

7.1.5.2 Capillary Column Dimensions and Film Thickness

The length of the column is an important parameter for resolution capability. Increases in column length improve the resolution capability but also increase retention times. Relatively short columns with very polar phases often give better resolution of unsaturated FAMEs than relatively long columns with nonpolar phases. Most of the columns used for FAME separation range between 25 and 50 m in length. Excellent separation of all the unsaturated FAMEs from various tissues has been demonstrated.
on a 25 m very-polar (CP®-Sil 88) column, whereas on a 50 m nonpolar column based on methylsilicone, separation of all the important unsaturated FAs could not be achieved.\textsuperscript{111–113}

Relatively short columns (25 m or shorter) can be used for rapid analysis of relatively simple FAME mixtures. A common vegetable oil containing FAs with CLs between 14 and 18 carbon atoms can be analyzed in less than 5 min on a short column.\textsuperscript{114}

The internal diameter and the film thickness of a WCOT capillary column influence its capacity, resolution capability and FAME retention times. Increasing film thickness increases the sample capacity of the column, the resolution capability and the retention times. In most cases, a film thickness of 0.25 µm will provide sufficient resolution capability (although the resolution capability, of course, depends primarily on the type of stationary phase).

Decreasing the internal diameter of the column increases the resolution capability of the column but increases retention times and reduces the column capacity.

If narrow-bore capillary columns (with thin films) are used, the amount of sample introduced into the column must be restricted by splitting the carrier gas at a large split ratio. However, most analyses can be performed on medium-bore capillary columns that have an internal diameter of 0.25 or 0.32 mm.

7.1.6 Identification of Fatty Acid Methyl Esters

The best way to identify FAMEs is to compare their retention times with those of individual purified standards. An alternative way of identifying FAMEs is based on their relative retention times or equivalent chain-length values.\textsuperscript{114} The former is defined as the ratio between the retention time of any FAME and that of a reference FAME (usually C\textsubscript{16}:0 or C\textsubscript{18}:0).

The use of equivalent chain-length values (based on Kovats’ retention index\textsuperscript{115–117}) results in a ready visualization of the position of a particular FAME relative to saturated straight-chain acids, 16:0, 18:0, 20:0, 22:0, 24:0. Values for FAMEs can then be calculated either from an equation or by plotting on semilogarithmic paper.

7.1.7 Quantification of Fatty Acid Methyl Esters

For detection of FAMEs, the FID is most convenient. The amounts of FAMEs are usually determined via the peak area. (The peak area of a given amount of FAME is not influenced by the peak shape provided that extremely strong leading or tailing does not occur. Electronic digital integration is the most accurate and reproducible means of quantifying peak areas.) Quantification is commonly carried out after calibration of the system with standards containing known amounts of FAMEs. FAME mixtures should be similar in composition to the samples to be analyzed.

A usual method for absolute quantification is the addition of a FAME not present in the sample as an internal standard. The internal standard should be selected according to the sample to be analyzed.

Because in most food samples FAs with 16 and 18 carbon atoms are predominant, C\textsubscript{17}:0 is a regular internal standard in the analysis of FAMEs.\textsuperscript{118} If the sample contains C\textsubscript{17}:0, other FAMEs such as C\textsubscript{19}:0, C\textsubscript{21}:0 or C\textsubscript{23}:0 can be used.\textsuperscript{119}

7.2 Argentation Thin Layer Chromatography

Ag-TLC is based on the ability of silver ions to form polar complexes reversibly with unsaturated centers in organic molecules such as lipids. It enables separation according to the number, geometrical configuration and position of DBs in molecules.

In Ag-TLC, both precoated and homemade plates can be impregnated with silver ions to give satisfactory separations. The adsorbent is commonly silica gel G.

FAs, usually as the FAMEs, can be separated according to the number and configuration of the DBs.

The choice of mobile phase depends on the separation required. Resolution of methylene-interrupted unsaturated FAs with up to three DBs can be achieved using benzene–hexane as the developing solvent.\textsuperscript{120–122} Separation of FAs with up to six DBs is possible with a single development of benzene–ethyl acetate while other methods involve double developments with hexane–diethyl ether–acetic acid mixtures or a two-stage development, first with a polar solvent (chloroform–methanol–water or hexane–diethyl ether mixtures) to separate FAs with three to six DBs, followed by a development suitable for FAs with fewer DBs.\textsuperscript{123–125}

Using HPTLC plates and toluene–acetonitrile mixtures as mobile phase, components with two to six DBs and 18, 20 and 22 carbons can be resolved into zones according to degree of unsaturation; within each zone there is separation of FAs apparently according to CL, although the position of the first DB in each ester may be the important factor (Figure 3).\textsuperscript{126}

All (n-6) polyunsaturated FAs can be separated, as are (n-3) polyunsaturated FAs. Also geometrical isomers with trans DBs are readily separated from the corresponding cis isomers, the former having greater mobility.\textsuperscript{127}

An important problem is the resolution of mixtures containing FAs with more than one DB with all possible combinations of geometrical isomers. For mixtures of C\textsubscript{18} FA isomers with zero to two DBs,
FOOD

8 ANALYSIS OF TRIACYLGLYCEROLS

8.1 Thin-layer and Conventional Column Chromatography

The most commonly employed methods for analysis of TAGs are Ag-TLC\textsuperscript{(132–134)} and RPTLC.\textsuperscript{(135)}

8.1.1 Silver Ion Thin-layer Chromatography

Since the first separations of TAGs by Ag-TLC,\textsuperscript{(136)} the technique has been used, either on its own or as a preliminary simplification step, to elucidate the structures of many fats and oils, including cocoa butter, cod liver oil, cottonseed oil, evening primrose oil, grape seed oil, lard, maize oil, milk fat, olive oil, orange seed oil (Figure 4),\textsuperscript{(137)} pepper seed oil, soybean oil, sunflower oil and tomato seed oil, as well as for studying the process of interesterification and the changes produced by heating.

This method is based on the ability of alkenic bonds to form $\pi$-complexes with silver ions, which permits the separation of substances with differing degrees of unsaturation.\textsuperscript{(138)}

![Figure 4](image-url)

Figure 4 Diagrammatic Ag-TLC separation of TAGs from orange seed oil. The silica gel G layer was impregnated with 0.5% methanolic AgNO\textsubscript{3} and plates were developed in open cylindrical tanks. Plate A, mobile phase of petroleum ether–acetone (8 ml, 100:6 v/v); plate B, petroleum ether–acetone (5 ml, 100:8 v/v) followed by petroleum ether–acetone (8 ml, 100:5 v/v); plate C, petroleum ether–acetone (4 ml, 100:7 v/v) followed by petroleum ether–acetone (15 ml, 100:4 v/v). Bands were visualized by exposing plates sequentially to bromine and sulfuryl vapors followed by heating to 180–200°C. (Reproduced by permission of the authors and La Rivista Italiana Delle Sostanze Grasse and redrawn from Tarandjiiska and Nguyen.\textsuperscript{(137)})

cis-monoenes overlapped with trans,trans-dienes under standard conditions.\textsuperscript{(128)} They could be resolved, however, by using silver benzene sulfonate-impregnated plates and by modifying the mobile phase. A similar mixture with the addition of conjugated dienes (trans/trans, cis/trans, cis/cis) could be resolved completely only by using two plates of differing AgNO\textsubscript{3} concentrations with large volumes of different developing solvents (petroleum ether–acetone and chloroform–methanol) in open tanks.\textsuperscript{(129)}

Ag-TLC can be also applied to a variety of substituted FAs including unsaturated epoxy, hydroxy, dihydroxy and halohydroxy FAs. One interesting separation is that of methyl 11-(R)-hydroxy-9(Z),12(Z)-octadecadienoate from the unresolved pair of methyl 9-hydroxy-10(E), 12(Z)- and 13-hydroxy-9(Z),11(E)-octadecadienoates in a study of the oxidation products from linoleic acid treated with a red algal enzyme preparation.\textsuperscript{(130)} Recently, hydroperoxides of methyl oleate have been converted to hydroxides and separated into cis and trans isomers by Ag-TLC prior to separation of the hydroxy positional isomers by HPLC and identification by GC ion trap MS.\textsuperscript{(131)}
Of species with the same total number of DBs, that in which the DBs are more concentrated in individual acyl residues has the slower mobility. TAGs containing linolenate are usually retained more strongly than those containing acyl groups with up to two DBs but with one more DB in total, although the order of species with trienoic acids can vary according to the nature of the mobile phase. The 20 possible species containing FAs with zero to three DBs (i.e. trisaturated to trilinolenate) can be totally resolved.

The thin layer is a silica gel slurry containing 5–25% AgNO₃ applied to a plate. The solution of glycerides is applied to the plates in the form of a streak, and the plate is developed using ether–benzene or chloroform–methanol mixtures. Under these conditions, saturated TAGs migrate together with the front, followed by the various groups of TAGs in order of increasing unsaturation.¹³⁹,¹⁴⁰

After separation, the TAGs are located by UV light and may be quantitatively recovered by elution of the respective bands; the composition of each TAG can be determined by its location on the chromatogram and analysis of its FAs by applying the usual methods of conversion to FAMEs and GC. A range of developing solvents can be used for resolving TAGs. These include benzene with cyclohexane, cyclooctane, diethyl ether or methanol, petroleum ether–acetone, tetrachloromethane–acetic acid, isopropyl alcohol–chloroform and toluene with chloroform, diethyl ether or hexane. Methanol (1%) in chloroform can be recommended for resolving components with up to six DBs, and increasing the amount of methanol to 5% for separation of more highly unsaturated species on a separate TLC plate.¹⁸

TAG isomers differing only in the position of the acyl moieties (at the sn-2 and sn-1/3 positions) can be resolved also, allowing the identification of species with specific FAs at the sn-2 position without the need for techniques such as enzyme hydrolysis. SSM–SMS, SSD–SDS and MSM–MMS pairs have been separated with the former member of each pair migrating the least (where D is unsaturated, M is monounsaturated and S is saturated). All these pairs and others (DDS–DSD and DDM–DMD) have been resolved by continuous development with chloroform–methanol in open tanks.¹⁴¹,¹⁴²

8.1.2 Reversed-phase Thin-layer Chromatography

RPTLC was first introduced into TAG analysis by Kaufman et al.¹⁴⁵ and it has been successfully used to resolve TAG mixtures according to their partition number (PN), which is given by Equation (2):

\[ \text{PN} = \text{CN} - 2n \]

where \( n \) is the number of DBs in the TAG molecule. The best resolutions have been achieved using stationary phases consisting of long-chain hydrocarbons or liquid paraffin and the quantification usually proceeds by indirect GC or spectrophotometric methods. Today, densitometry is the method of choice for quantification of the compounds separated by TLC. Since charring is most often used for the direct densitometric determination of TAGs, long-chain hydrocarbons and liquid paraffin are unsuitable as the stationary phase. Reverse-phase-chromatographic systems must, therefore, combine good selectivity with the possibility of direct densitometric quantification. Plates are cooled and stored in a desiccator over phosphorus pentoxide until silanization. Silanization of the layer is achieved by placing the plates in a closed chamber over dimethylchlorosilane vapors for a certain length of time. The plates are washed by elution with methanol and dried at 110°C for 1 h and then stored in closed glass boxes without any special precautions. Densitograms are carried out on a densitometer by zigzag scanning in transmission mode at 450 nm using a 1.2 mm slit.

To ascertain which systems are optimal for TAG analysis, various layer types, mobile phases and detection methods have been tested under identical conditions using a variety of TAG standards.¹⁴⁴ Three different types of layer (plain unimpregnated silica gel TLC, silica gel layers impregnated with AgNO₃ by the manufacturer or in the laboratory, and silica gel layers with chemically bonded C₁₈ groups) were compared by Masterson et al.¹⁴⁵ using chromatographic standards and applied to analyses of hen’s egg yolk, lard and snail extracts.

Ag-TLC plates can be prepared by hand-dipping the silica gel plates into a Desaga glass dipping chamber containing a 2.5% solution of AgNO₃ in methanol, followed by activation in an oven at 110°C for 1 h just before use. Commercially prepared plates (20 cm × 30 cm) impregnated with 10% AgNO₃ were also used.

Standards were chosen based on both saturation class (S₃, S₂M, M₃ and D₃) and PN. All standard solutions must be prepared at a concentration of 1.0 g l⁻¹ in chloroform.

The best separations are achieved using isopropyl alcohol–chloroform with Ag-TLC plates and mixtures of isopropyl alcohol–chloroform (1.5 : 98.5) with plain silica gel TLC and acetonitrile–methyl ethyl ketone–chloroform (50 : 35 : 15).

8.2 Separations with Column Chromatography

Neutral and polar lipid classes can be separated and isolated for subsequent analysis using column chromatographic modes, creating selectivity in the isolation of compounds by altering the solid/support solvent system so that a unique interaction exists between the compound to be isolated and the functional group of the solid phase.
Compounds that are very diverse in chemical structure may differ greatly in their interactions with the solid-phase surface moieties, whereas compounds that are chemically similar may exhibit only subtle, though still exploitable, differences. Therefore, by varying the solvent environment (e.g. polarity) around the solid phase, lipids can be selectively isolated with a high degree of purity and recovery. The most widely used columns are aminopropyl bonded phase (Bond Elut) columns that may or may not be placed in a vacuum curve to enhance the separation rate. The mixtures used with this type of column to elute TAGs are 1% diethylether and 10% methylene chloride in hexane, and the quantity used to elute the TAGs is 8 ml.\textsuperscript{146,147}

8.3 Thin-layer Chromatography with Flame Ionization Detection

TLC with FID is a simple, easy-to-use analytical method that is sufficiently sensitive to produce good separations and is suitable for the quantification of complex lipids. In TLC/FID, the sample is spotted on a quartz rod coated with silica gel, developed chromatographically and finally subjected to detection by FID as the rod is passed through a hydrogen flame.

The response factors for various lipids differ and depend upon such variables as sample volatility, amount of material analyzed, its composition and the rate of passage of the Chromarod through the flame.\textsuperscript{148–151}

Quantification of lipids by FID after separation by TLC on Chromarods can be improved by the use of internal standards that reduce rod-to-rod variation but the relative response of different lipid classes to an internal standard has not been found to be constant: it varies with the amount of sample applied, the ratio of sample to internal standard and the scanning speed.\textsuperscript{152}

Since latroscan FID sensitivity varies depending upon the substances to be detected, it is necessary to obtain a suitable calibration curve prepared on the basis of the peak area measurements and the amounts of the components.\textsuperscript{153}

The latroscan technique has proven highly effective in separating phospholipids, cholesterol, TAGs and FAs, but the system may not always be so effective in separating TAGs.\textsuperscript{154,155}

8.4 Enzymatic Methods

Analysis of TAGs has been simplified by the introduction of enzymatic methods, which have been automated to provide analysts with quick, easy and direct procedures. Enzymatic methods are based on determinations of the glyceral portion of the TAG molecules after hydrolysis to remove the FAs. Dosing takes place in the following three stages: TAG emulsion, complete hydrolysis by a lipase and a stearase, and indirect spectrophotometric measurement of the glyceral at 340 or 500 nm.\textsuperscript{156}

The TAG can be determined using either a dehydrogenase system in which oxidation of NADH is followed at 340 nm or the oxidase/peroxidase system in which formation of a blue color is followed at 500 nm (Scheme 1).\textsuperscript{157,158}

8.5 Gas Chromatography

The first studies on separations of TAGs using GC were carried out by Fryer et al.\textsuperscript{159} and Hubber.\textsuperscript{160} Kuksis and McCarthy\textsuperscript{161} improved the separation technique by employing direct injection onto the column.

In the 1960s, TAG analysis was carried out on columns packed with dimethyl polysilene (OV-1, OV-101, JXR, S-30) or phenyl methyl polysiloxane (OV-17, SE-52). The internal diameter was 2.5–3.5 mm. The column length depended upon the type of separation. For TAGs above C\textsubscript{40}, 0.5–0.7 m columns were used. Columns longer than 2.0 m are impractical for separating TAGs above C\textsubscript{48}.

\end{align*}
\]

**Scheme 1** Enzymatic assay of TAG. The dehydrogenase system is followed by $A_{340}$, which decreases as NADH is oxidized. The oxidase/peroxidase system generates a blue color that is followed at 500 nm.
Since the 1970s, capillary GC using apolar columns (OV-1, SE-52, SE-54) has become a routine tool for characterization of the TAG profile of fats.\(^{162}\) TAG separation on apolar silicone phases is based mainly on molecular mass differences (CN determinations), whereas unsaturation barely contributes to peak retention.\(^{163}\)

The columns used at the end of the 1990s, have chemically bonded, polarizable stationary phases; their length varies from 5 to 25 m, with an internal diameter ranging from 0.2 to 0.32 mm. Column length must increase as the molecular mass of the TAGs to be separated increases. The stationary phase used has an upper temperature limit of 360 °C. Hydrogen is the most commonly used carrier gas with this type of column, and the hydrogen flow rate decreases significantly with increasing temperature. Using hydrogen as the carrier gas affords several advantages over nitrogen, used in packed columns and in the earlier capillary columns. One such advantage is a lower elution temperature compared with that for nitrogen and helium, leading to shorter analysis times and less thermal decomposition.

On employing isothermal chromatographic conditions to analyze a mixture of TAGs with different vapor pressures or long retention times at high temperature, the amount of the stationary phase and column efficiency (length) are selected so as to achieve good separation of the most volatile components. With TAGs, the main problem is always to reduce the analysis time for isothermal chromatography; however, longer columns are needed to achieve separation of the low-molecular-mass components, while retention times for high-molecular-mass TAGs are very extended, and certain ones may not elute. When programmed temperature chromatography is used, the retention times for a series of compounds with the same CN generally increases linearly with the number of carbon atoms rather than exponentially as occurs in isothermal chromatography.

### 8.5.1 Stationary Phase

The high-temperature polarizable phenylmethylsilicone liquid phases permit high-temperature GC separation of natural TAGs based on degree of unsaturation.

The phenylmethylsilicone liquid phase becomes sufficiently polar as the temperature increases above 290 °C, as indicated by the longer retention of unsaturated compared with saturated TAGs. As the temperature increases, the molecular species of TAGs are eluted in order of increasing number of DBs per molecule.

Wide-bore capillary columns containing polarizable phenylmethylsilicone can be used for high resolution of palm oil TAG fractions with automated cold on-column injection; polarizable phase capillary GC can be also used in combination with MS for the determination of the elution profiles and for identification of the eluted species of natural TAGs.

Identification of closely eluting or overlapping GC peaks can be obtained by prior Ag-TLC resolution. This part of the analytical system can be applied sequentially to the resolution and quantification of the diacylglycerol moieties of glycerophospholipids and TAGs, and subsequently to their FA moieties.\(^{6}\) Figure 5 illustrates the application of polarizable capillary GC in combination with Ag-TLC for the resolution of butteroil TAGs.\(^{164}\)

With a polarizable methylphenylsilicone stationary phase, the CN sequence is retained, but unsaturation now contributes to the fine structure of each CN fraction. For example, the order of elution becomes tin-palmitin, palmitoyl-oleoyl-palmitin and palmitoyl-linolenoyl-palmitin, all of which have saturated acids on the molecule; separation by triplets takes place according to the unsaturation of the middle acid.\(^{165}\) Vegetable and animal fats can be analyzed using this type of column, separating substances with the same number of carbon atoms but differing by only a single DB.\(^{166}\)

### 8.6 High-performance Liquid Chromatography

#### 8.6.1 Reversed-phase High-performance Liquid Chromatography

RPHPLC is the principal chromatographic technique for separating mixtures of TAGs. TAGs are separated based on CL and the degree of unsaturation of the FAs. The PN is used to characterize TAG molecules and determine their elution (Equation 2).\(^{167}\)

Different workers have developed other parameters analogous to PN for molecularly discriminating between TAGs with the same PN value, mainly to improve identification of chromatogram peaks.\(^{168–170}\)

Considerable progress has been now made in improving RPHPLC methodology, overcoming the difficulties encountered in separating the TAGs in natural fats.

#### 8.6.1.1 Separation of Triacylglycerols of Similar Partition Number

Mixtures of TAGs composed of FAs differing only minimally in CL and degree of unsaturation have the same PN value. Despite the improvements in efficiency achieved using octadecyl silanized columns with a particle size of 3 µm connected in series and elution gradients with acetone as the organic modifier, poorly resolved or even unresolved TAG pairs and groups still exist, especially in highly complex mixtures of natural fats such as milk fat and fish oils.\(^{171}\)

#### 8.6.1.2 Separation of Triacylglycerols with Marked Differences in Structure

Simultaneous analysis of TAGs differing markedly in molecular structure (i.e. short-

Inset: 15% Ag-TLC resolution of R-4 distillate in chloroform plus 0.75% ethanol. Peak identification band 1: 7, 8-14-14 + 8-12-16 + 10-14-12; 8, 6-14-16 + 6-12-18; 14, 10-14-14 + 10-12-16; 15, 8-14-16 + 8-12-18; 16, 6-16-16 + 6-14-18; 21, 10-14-16 + 12-14-14; 22, 8-16-16 + 8-14-18; 23, 6-16-18; 29, 10-16-16 + 10-14-18; 30, 8-16-18; 35, 10-16-18 + 12-16-16 + 14-16-14; 40, 14-16-16; 44, 16-16-16; 45, 16-16-18. Peak identification band 5: 6, 12-18:1-6 + 14-16:1-4; 12, 12-18:1-6 + 14-16:1-6; 13, 14-18:1-4 + 16-16:1-4; 20, 18; 1-14-8 + 12-16:1-10; 21, 18; 1-16-4 + 16:1-18-4; 27, 18; 1-14-8 + 16:1-14-10; 28, 18; 1-16-6; 29, 18; 1-18-4; 34, 10-18-14 + 12-16:1-14; 35, 18; 1-16-8; 38, 10-18-1-16; 41, 16-18:1-12 + 14-14-18:1; 44, 14-16-18:1; 46, 16-16-18.1. GC conditions: column, flexible quartz capillary (25 m x 0.25 mm internal diameter, RSL-300 custom made); carrier gas H2. On-column injection; temperature 40°C, ballistically heated to 290°C, at 10°C min⁻¹ to 330°C and at 2°C min⁻¹ to 350°C. (Reprinted from J.J. Myher et al., 'Identification of the More Complex Triacylglycerols in Bovine Milk Fat by Gas Chromatography–Mass spectroscopy using Polar Capillary Columns', J. Chromatogr., 452, 93–118, Copyright (1988), with permission of Elsevier Science.)
LIPID ANALYSES IN FOOD

medium- and long-chain TAGs with differing degrees of unsaturation spanning a broad range of PN values) is difficult because of problems in achieving, simultaneously, both good resolution of the least strongly retained TAGs and reasonable analysis times and elution in narrow chromatographic bands for the most strongly retained TAGs.\(^{(172)}\)

8.6.1.3 Detection of Triacylglycerols at the Column Outlet

Refractive index and UV detectors were most commonly used in HPLC analyses for fats.\(^{(173,174)}\) Consequently, it has been necessary to develop new systems such as light-scattering detectors and combined HPLC/MS. As pure standards are usually unavailable, and incomplete resolution of critical groups makes peak identification difficult on the chromatograms, combining HPLC with MS may furnish valuable information on the structure of TAGs.

The stationary phase yielding the best separations is octadecylsilane supported on spherical particles of silica gel. While good separations have been obtained using a particle diameter of 5 \(\mu m\), reducing the diameter to 4 and 3 \(\mu m\) improved selectivity between chromatogram peaks for columns of similar size.

Octadecylsilane columns are normally 15 to 30 cm long with an internal diameter of 4–5 mm. Two and three columns have been connected in series to improve separations of the TAGs from natural fats. Increases in column length are limited by the rise in column head pressure and the substantially longer analysis times.

8.6.2 Mobile Phase

Mobile-phase composition is the most important chromatographic factor affecting the separation of TAGs in RPHPLC because of the small variability in the type of stationary phase employed. Most researchers have elected to use a mobile phase comprising an organic base solvent and an organic modifier. Acetonitrile is the most widely used organic base solvent, though \(n\)-propionitrile has sometimes been preferred.\(^{(175)}\)

Organic modifiers are added to improve the solubility of the TAGs in the base solvent of the mobile phase, to bring about changes in mobile-phase polarity and to increase peak selectivity. When choosing an organic modifier, the following factors should be taken into account, in addition to the nature of the solvent:

- whether the mixture consists of single or multiple components
- the percentage of organic modifier in the mobile phase
- whether that percentage is constant or varies over the course of elution.

Under both isocratic and gradient elution conditions, an increase in mobile-phase polarity leads to an increase in retention times and in the selectivity of pairs or groups of TAGs with the same PN: there are linear relationships between the logs of the capacity factor \((k)\) and TAG selectivity and the percentage organic modifier in the mobile phase, irrespective of solvent type and elution conditions.\(^{(176)}\)

The choice of organic modifier, single or multiple component composition of the modifier, proportion of modifier to base solvent, and possible variations in that proportion during elution depends mainly upon the type of TAG to be separated and the detection system employed. Although many different solvents have been used as the organic modifier, acetone is most commonly employed because of its effect in improving the selectivity of TAG pairs or groups with the same PN. Acetone cannot be the modifier with UV detectors because of its strong absorbance at the wavelengths absorbed by the TAGs (200–237 nm).

In such cases, hexane, \(n\)-propanol, ethanol and methyl-\(\text{tert-}\)-butylether have been proposed as organic modifiers and have produced good separations of complex mixtures.

Initially, TAG analysis was carried out using a constant proportion of organic modifier in the mobile phase with refractive index detection.\(^{(177,178)}\) Those conditions of analysis yielded relatively satisfactory separations of simple mixtures of TAGs, such as most vegetable oils, which have mean composition of 5–7 FAs and 15–20 TAG species. Although the resolution of most such TAGs was good, certain critical pairs remained unresolved, e.g. LLL–LnLO and LnLO–LnLP for PN 42; LLO–LnOO, LnOO–LnSt and LLSt–LnOP for PN 44; LLSt–LOP for PN 46; and OOO–LOSt and OOP–LSiP for PN 48 (where L is linoleic acid, Ln is linolenic acid, O is oleic acid, P is palmitic acid and St is stearic acid).

Varying the proportion of organic modifier during elution has been proposed as a solution when analyzing more complex natural mixtures, where there is a much greater likelihood of encountering molecules with the same PN value because of the larger number of FAs than found in vegetable oils and, usually, the much higher number of TAG types.

Gradient elution systems are intended to ensure good solubility of all the TAGs present in the mixture in the mobile phase throughout the run, reduce retention times for highly saturated TAGs and, at the same time, achieve good resolution of critical pairs with the same PN.\(^{(179)}\) Employing two 5 \(\mu m\) octadecylsilane columns, a linear gradient of 20 to 80\% \((v/v)\) dichloromethane–acetone \((3:1\ v/v)\) in acetonitrile and light-scattering detection, it is possible to achieve excellent separation of the TAGs in vegetable oils and animal fats (Figure 6).\(^{(180)}\)
Figure 6 HPLC separation of soybean oil (a) and olive oil (b) TAGs using two 5µm Lichrosphere 100 CH-100 SUPER columns (250 mm × 4.0 mm internal diameter) connected in series. Column temperature ambient; mobile-phase linear gradient of 20 to 80% (v/v) dichloromethane–acetone (3 : 1 v/v) in acetonitrile for 60 min at a flow rate of 1.0 ml min⁻¹; mass detection. (Reproduced from Perrin and Prevot. Permission sought.)

Despite the enhancement in resolution brought about by elution gradients, complex mixtures of natural fats still contain many unresolved TAG pairs or groups with the same PN, and this is one of the most important unsolved analytical challenges remaining today. However, nonlinear gradients and specific-step gradients have been used, chiefly with a view to improving the separation of critical pairs.\textsuperscript{181}

Normally, the mobile-phase flow-rate ranges from 0.5 to 2.0 ml min⁻¹.

Under isocratic elution conditions, small increases in flow rate enhanced the resolution of certain critical pairs.\textsuperscript{171,176}

8.6.3 Sample Solvent and Column Temperature

The sample solvent may exert a major effect on the resolution of a chromatographic system. Various solvents reveal substantial differences according to the nature of the injection solvent and the mobile phase. The effect of the solvent on the chromatographic resolution can be explained in terms of the theory put forward by Horvath and Melander.\textsuperscript{182} They suggested that in order for a dissolved solute molecule to be carried by the mobile phase it must create room and this gives rise to a reduction in free volume. Chloroform is suggested as the sample solvent when working with mobile phases in which solubility of TAGs, particularly highly saturated TAGs, is poor.

Most RPHPLC analyses of TAGs can be done with the column at ambient temperature; however changes in column temperature will result in changes in chromatographic resolution. Higher column temperatures decrease retention times and selectivity for TAGs, especially for critical pairs with the same PN.

Although lower temperatures result in better separation of the TAGs, the most highly saturated TAGs may precipitate out of the mobile phase, and consequently the preferred working temperatures is at least 30°C.

Because the choice of column temperature represents a compromise designed to ensure good solubility and good selectivity of critical pairs with the same PN, it is advantageous to use temperature gradients to analyse complex mixtures of TAGs spanning a broad range of PN values.\textsuperscript{183} Figure 7 illustrates the separation of butterfat TAGs using a temperature gradient of 10 to 55°C with a 5µm octodecylsilane column (250 × 4.0 mm internal diameter) and a mobile phase of acetonitrile–acetone (50:50 v/v).\textsuperscript{183}

8.6.4 Detectors

Refractive index detectors have been used in most analyses of simple mixtures of TAGs under isocratic
conditions of elution. However, they have low sensitivity and low stability because of their sensitivity to changes in temperature and pressure and cannot be used with gradient elution because they are affected by the composition of the mobile phase.

Plattert\textsuperscript{184} used infrared detectors at 5.75 µm, especially for qualitative purposes. Although this type of detector is suitable for gradient elution, substantial baseline drift may occur.

Absorption in the UV region 200–237 nm provides for highly sensitive detection of TAGs and good detector stability and can be used with gradient elution.\textsuperscript{185} Considerable baseline drift may occur when the gradient composition of the mobile phase varies over a broad range.\textsuperscript{186} UV detector response in that region of the spectrum is mainly to weakly chromophoric ester bonds with a lower molar extinction coefficient. However, UV absorption can be considerably enhanced by interactions between the carbonyl groups and the DBs.

Moving-fire FIDs are not widely used or available commercially for HPLC analysis and may be subject to shortcomings involving low sensitivity because only a small portion of the solvent eluting from the column can be used for FID detection.\textsuperscript{187}

Recently, RPHPLC analyses of TAGs can be performed using mass detectors.\textsuperscript{188,189} Mass detection is based on light scattering by solute molecules following nebulization of the column eluate and evaporation of the solvent.\textsuperscript{190,191} Mass detection can be used with gradient elution and nonaqueous solvents and does not undergo baseline drift. Composition of the mobile phase, elution rate, nebulizer gas (normally compressed air) flow rate and solvent volatilization temperature all have an important influence on TAG response during mass detection.

Chemical detection by means of post-column reaction derivatization has seldom been used for TAG detection in HPLC. Mass detector also provides valuable information on TAG structure. Chemical ionization mass spectra have successfully identified all the major TAGs together with the sufficiently resolved minor TAGs in various natural fats and oils.

\subsection{8.6.5 Identification of Molecular Species}

One of the most important problems in RPHPLC of natural samples of TAGs is the identification of the molecular species in the peaks on the chromatogram. Wada et al.\textsuperscript{167} established a linear relationship between the capacity factor \((k)\) values of chromatographic peaks and the PN values of the TAGs. In addition, aspects of the theoretical prediction and identification of the TAGs in the peaks have been examined.

On the basis of their relative retention times, using an experimental linear relationship between relative retention time and the total number of carbons in saturated TAGs, Herslof et al.\textsuperscript{168} estimated theoretically the equivalent carbon number (ECN) for unsaturated TAGs.

This is defined in the same way as the PN (Equation 2) as shown in Equation (3):

\[
\text{ECN} = \text{CN} + a'n
\]

where \(n\) is the number of DBs in the TAG and \(a'\) is a constant. The value of the constant \(a'\) varies with the chromatographic system. However, it may take on values approaching 2; when \(a' = 2\), the PN and ECN have the same value.

The value of \(a'\) can be calculated from the linear relationship between \(\log k\), \(\text{CN}\) and \(n\) (Equation 4):

\[
\log k = a'n + b'\text{CN} + c'n
\]

The value of \(a'\) is equal to \(c'/b'\).\textsuperscript{192}

The parameters PN and ECN have generally been used in RPHPLC to characterize TAG molecules. However, TAGs with the same PN can be differentiated by ECN.

The preceding relationships are calculated for isocratic elution. Consequently the estimation of ECN is not appropriate for gradient elution, as TAGs of very similar molecular characteristics may elute in descending order of ECN. In such cases, it has been proposed that the ECN can be estimated by a second-degree function using CN and \(n\) (Equation 5):\textsuperscript{193}

\[
\text{ECN} = \text{CN} + d'\text{CN}^2 + e'n + f'n^2
\]
Marini and Balestrieri have established a theoretical CN, analogous to the PN and ECN, calculated from the CN and a function depending upon the degree of unsaturation of the FAs.\(^{(194)}\)

On analyzing pure standards of simple TAGs and mixed TAGs obtained by transesterification of the former, it is possible to obtain a linear relationship between what is termed equivalent CL \(L\) (Equation 6):\(^{(171)}\)

\[
L = g' + h' \log a_0
\]

The value of the equivalent CL \(L\) for the TAGs in the chromatogram is calculated from the experimental value of \(a_0\) for the peaks; it can then be used to estimate the molar FA composition of the peaks for a natural fat.

The procedure for predicting the TAGs in RPHPLC peaks derived from natural fat based on the CN is very complicated for large numbers of FA constituents (e.g. more than seven), since the variety of possible molecular species, even taking \(sn\)-stereospecific positions to be equivalent, is extremely high.

A matrix model using six variables, for the CL and number of DBs for each of the three acids esterifying the glycerol, taking \(sn\)-stereospecific positions as equivalent, has been developed by Takahashi et al.\(^{(192,195,196)}\) and is given in Equation (7):

\[
\log k' = i' + j_1'CL_1 + j_2'CL_2 + j_3'CL_3 + z_1'DB_1 + z_2'DB_2 + z_3'DB_3
\]  

Applying partition chromatography theory, they found a linear relationship between the log of the relative retention time for TAGs and potential relative retention indices for each constituent FA.

The IUPAC Commission on Oils, Fats and Derivatives undertook development of a method for and a collaborative study in the determination of triglycerides in vegetable oils by liquid chromatography (LC). Three collaborative studies were conducted from 1985 to 1987. Refinements were made in the method after the first collaborative study, and the second and third collaborative studies demonstrated that the method produces acceptable results. Materials studied were soybean oil, almond oil, sunflower oil, olive oil, rapeseed oil and blends of palm and sunflower oils and almond and sunflower oils. Six test samples were analyzed by 18 laboratories from 11 countries in the second study; four test samples were analyzed by 16 laboratories from 12 countries in the third study. The method for determination of triglycerides (by PN) in vegetable oils by LC was adopted first by AOAC International as an IUPAC–AOC–AOAC method.\(^{(197)}\)

Triglycerides in vegetable oils are separated according to ECN by RPHPLC and detected by differential refractometry. Quantification is by area normalization. Elution order is determined by calculating ECN (Equation 2). The ECN can be calculated more accurately by taking the origin of the DBs into account (Equation 8):

\[
ECN = CN - d_o n_o - d_l n_l - d_m n_m
\]  

where \(n_o, n_l\) and \(n_m\) are number of DBs of oleic, linoleic and linolenic acids, respectively, and coefficients \(d_o, d_l,\) and \(d_m\) are calculated from reference triglycerides. Under the conditions of this method, ECN approximates (Equation 9):

\[
ECN = CN - (2.60 \times n_o) - (2.35 \times n_l) - (2 - 17 \times n_m)
\]

With several reference triglycerides, resolution \(\alpha\) can be calculated with respect to triolein (Equation 10):

\[
\alpha = \frac{RT_i}{RT_{triolein}}
\]

Using reduced a retention time where RT is retention time. \(RT_i = RT_l - RT_{solvent}\). The retention values for all triglycerides of FAs contained in reference triglycerides (Figure 8) can be determined by a graph of log \(\alpha\) versus \(n\).

8.6.6 Argentation Chromatography

Argentation chromatography separates TAGs according to their degree of unsaturation, unlike RPHPLC in which the separation is more complex and depends on the CL of the constituent FAs in addition to the degree of unsaturation. The basis for TAG separation is the ability of the \(\pi\)-electrons in the DBs on the FA chains to interact with the silver ions on the stationary phase and form stable polar complexes. As the number of DBs in the molecule increases, so does the complex-formation effect and hence retention.\(^{(18)}\)

Of all the factors influencing HPLC techniques, the stationary phase is unquestionably the main factor in Ag-TLC. The silver ions may be added to the stationary phase in one of two ways: by impregnating the silica-gel support with a silver salt, normally AgNO\(_3\) or by bonding silver ions to the phase by means of an ion-exchange phase.

Silica-gel columns impregnated with AgNO\(_3\) were the first to be used. Impregnation with AgNO\(_3\) has varied from 5 to 10\%. At higher values chromatographic resolution is not improved, and at lower ones the silica-gel adsorption activity increases considerably, resulting in peak tailing.\(^{(43,198)}\)

Stationary phases consisting of phenylsulfonic groups chemically bonded to the silica gel appear to be the most advantageous form. Such columns are available in acid or sodium salt form and must first be neutralized by washing with sodium or ammonium hydroxide before treatment with aqueous sodium nitrate.
The silver ion content depends upon the number of bonded sulfonic acid groups and the degree of substitution of the initial cation by silver ions.

The composition of the mobile phase exerts a decisive influence on TAG separations because of solute retention on these columns. This occurs by mixed interaction with the more highly polar TAG groups involving the formation of complexes with the silver ions and adsorption by the unbound polar groups in the support. Consequently, solvents such as benzene, toluene and acetonitrile appear to interact preferentially with the silver ions and interfere with the interactions with the DBs. By comparison, methanol, isopropyl alcohol and acetone may block interactions with the unbound polar groups on the support.

Mass or light-scattering detectors and moving-flame FID can be used in TAG analysis by argentation HPLC because they do not limit the choice of solvents for the mobile phase, which can be problem with UV detectors and acetone. They also afford good stability and sensitivity when using complex elution gradients with mixtures of three or more solvents.\(^{43}\)

### 8.7 Stereospecific Analysis

The physical and chemical properties of fats are related both to FA composition and FA distribution in the TAGs. Consequently, it is necessary not only to identify the acid constituents but also to determine the distribution of those acids in the TAG molecule. This distribution characterizes fats, since there may be several different patterns of distribution on the glyceride molecule for a given FA composition. This change in distribution produces fats with entirely different properties, particularly physical ones.

If we consider the case of a fat composed of only two FAs, A and B, and take positions 1 and 3 on the glycerol molecule to be identical and interchangeable, the two FAs can form six different TAGs (four if no distinction is made between isomers): AAA (A\(^3\)), AAB and ABA (A\(_2\)B), ABB and BAB (AB\(_2\)) and BBB (B\(^3\)). With three FA constituents, A, B and C, the number of possible TAGs rises to ten (excluding isomers): A\(^3\), B\(^3\), C\(^3\), A\(_2\)B, AB\(_2\), A\(_2\)C, AC\(_2\), B\(_2\)C, BC\(_2\) and ABC. This rises further to 18 if isomers are included.

The number of possible TAGs climbs rapidly with the number of FA constituents; consequently, the complete analysis of a fat composed of three to five main FAs and a large number of minor FA constituents is practically impossible.

The problem is customarily simplified in various ways, the two most common being to avoid considering isomers and to determine closely related groups of TAGs rather than pure TAGs. The categories or groups established at any given time will depend upon available analytical techniques. Accordingly, initially only four categories of TAGs were determined, based on the number of saturated (S) and unsaturated (U) acyl groups they contained. These groups were designated S\(_3\), S\(_2\)U, SU\(_2\) and U\(_3\). With currently existing methods, it is possible to identify additional, more specific categories.
In addition to the preceding simplifications, it is nearly always necessary to establish specific cases, depending upon the analytical method employed, to enable the TAG composition to be calculated from the data obtained.

The goal of analyzing FA distribution is to determine the TAG composition of fats and to develop models of FA distribution on natural glycerides in order to elucidate biosynthetic pathways and thus predict the approximate glyceride composition of a given fat. With advances in analytical techniques, new theories explaining the distribution of acyl remnants have been put forward. Currently, such theories are much more consistent for vegetable fats, synthesized entirely in situ by the plant, than for animal fats, which are partly endogenous and partly exogenous.

The first hypothesis explaining the distribution of FAs in natural TAGs was the theory of the formation of simple TAGs, that is, each chemical species consisting of a single FA only: triolein, tripalmitin, etc. There followed several more theories. The theory of minimal distribution postulates the formation of the smallest possible number of pure TAGs. The rule of even distribution, developed by Hilditch, postulates that FAs are distributed as widely as possible among all TAGs (namely, an acid accounting for 33.3% of the total will be present in all TAGs only once, an acid accounting for between 33.3 and 66.6% will be present between one and two times, and simple TAGs composed of that acid will be formed only when the share contributed by that acid exceeds 66.6%). The random distribution theory holds that FAs are statistically distributed among all the hydroxyl groups on all the glycerol molecules. The random distribution or restricted statistical distribution theory is a modified version of the random distribution theory that was developed by Kartha to keep the content of the completely saturated glycerides calculated to within the bounds of the experimental range. Finally there are the theories of random distribution at position 2 and random distribution at positions 1 and 3.

The theory of random distribution at positions 1 and 3 was developed independently by Vander Wal and Coleman and Fulton from newer data obtained by hydrolysis using pancreatic lipase and is based on the following assumptions:

- positions 1 and 3 are equivalent
- the FA composition at position 2 and positions 1 and 3 is different and independent
- the acids occupying position 2 as well as those occupying positions 1 and 3 are randomly distributed.

Using these assumptions, it is possible to compute the TAG composition of natural fats from the data on the FA composition at different positions obtained by lipolysis.

If the total concentration of an acid, A, in mole % in the TAGs is known and the concentration for that same acid at position 2, A2, is known, the concentration at positions 1 and 3 will be given by Equation (11):

$$A_1 = A_3 = \frac{3}{2A} - \frac{1}{2A_2}$$

and so on for the remaining acids. From this the molar concentration of the different TAGs can be calculated. AAA is \([A_1][A_2][A_3] \times 10^{-4}\); ABA is \([A_1][B_2][A_3] \times 10^{-4}\); AAB is \(2 \times [A_1][A_2][B_3] \times 10^{-4}\); ABC is \(2 \times [A_1][B_2][C_3] \times 10^{-4}\); ACB is \(2 \times [A_1][C_2][B_3] \times 10^{-4}\); and BAC is \(2 \times [B_1][A_2][C_3] \times 10^{-4}\) (where square brackets indicate concentration; i.e. \([A_1]\) is the concentration of \(A_1\)).

Enzymatic lipolysis using porcine pancreatic lipase produces glycerol and FAs in a stepwise manner via the intermediate di- and monoglyceridic stages (Equation 12):

TAGs $\rightarrow$ 1,2-Diglycerides + 2,3-Diglycerides + (FAs) $\rightarrow$ 2-Monoglycerides + (FAs) $\rightarrow$ Glycerol + (FAs)

This approach has been applied to a number of vegetable and animal fats and has shown that unsaturated C18 acids (oleic, linoleic and linolenic acids) occupy nearly all available position 2 sites, whereas saturated and unsaturated C20 and C22 acids are present only at positions 1 and 3.

Based on these observations, certain workers have suggested that in vegetable fats position 2 is preferentially acylated by unsaturated acids with 18 carbon atoms and positions 1 and 3 are acylated by the remaining acids and those unsaturated C18 acids that are unable to find a free position 2 site.

Within these limitations, acyl groups follow a pattern of statistical or random distribution. Calculating the composition of the basic glyceridic groups, S,S,U; S,U2 and U3, where S is saturated and U unsaturated (including unsaturated acids with 20 and 22 carbon atoms), shows that the results obtained using random distributions at position 2 and positions 1 and 3 are in better agreement with lipolysis data than the results for the statistical and even distribution theories.

8.7.1 Stereospecific Analysis of Triacyl-sn-glycerols

HPLC determination of the sn positions occupied by FAs on the triacyl-sn-glycerol molecule is rather complicated, since most analyses require, first, careful sample preparation and, second, GC analysis of the FAs obtained from the enantiomeric fractions separated by preparatory HPLC.
Sample preparation entails prior partial hydrolysis of the triacyl-sn-glycerols to obtain mono- and/or diacyl-sn-glycerols, normally by means of the Grignard reaction with ethylmagnesium bromide, followed by formation of derivatives of the mono- and diacyl-sn-glycerols and isolation by solid-phase extraction or TLC. HPLC analysis of the mono- and diacyl-sn-glycerol derivatives, and in some cases of the derivatives of the triacyl-sn-glycerols themselves, has been performed using normal-phase adsorption chromatography, reversed-phase chromatography and chiral-phase chromatography.

1 INTRODUCTION

A general overview of the possibilities for using the HPLC technique in food analysis is presented. Because the subject is extensive this article can only portray generalities. For further information the reader should consult the referenced books and articles.

This article begins by discussing various methods of sample preparation, cleanup and, if necessary, derivatization techniques. In subsequent sections the separation, analysis, and detection of different nutrients, residues, and additives in foods are treated.

2 HIGH-PERFORMANCE/PRESSURE LIQUID CHROMATOGRAPHY

HPLC (high-pressure or high-performance liquid chromatography) instruments comprise different parts: solvent reservoirs, pumping units for isocratic or gradient analysis, injection devices, columns and detectors.

In adsorption or normal-phase liquid chromatography (NPLC) the stationary phase (packings) is polar: silica, alumina or polar-bonded silicas (cyanopropyl-bonded, aminopropyl-bonded or diol-bonded silicas). Different solvents are used as mobile phases such as pentane and hexane.

In reversed-phase liquid chromatography (RPLC) the stationary phase (C8, C18, phenyl bonded) is apolar. An alkyl group is bonded onto silica gel. A wide variety of stationary phases exist. The mobile phase is hydrophilic. Mixtures of water and organic modifiers such as methanol, acetonitrile, and tetrahydrofuran are used.

Three modes exist in ion chromatography (IC):

- Ion exchange – Cation or anion exchangers separate samples by their charges. Cation and anion exchangers are either strong (SCX, strong cation exchanger and SAX, strong anion exchanger) or weak (WCX, weak cation exchanger and WAX, weak anion exchanger).
- Ion exclusion – Nonionic compounds are separated on an ion-exchange packing through differences in acid strength, size, and hydrophobicity.
- Ion pairing – This is a combination of a RP (reversed-phase)-packing with a mobile phase of an aqueous organic mixture and an ion-pairing agent. The agent forms an ion pair with the analyte with increased lipophilicity.

Size-exclusion chromatography (SEC) separates molecules by their size. Synonyms are gel permeation chromatography (GPC) and gel filtration chromatography (GFC).
A wide choice of special phases exist for chiral or enantiomeric separations. Silver IC separates positional and configurational isomers of fatty acids. In isocratic elution the composition of the mobile phase is constant; in gradient elution the solvent strength is increased.

Hyphenated techniques consist of coupling different techniques such as liquid chromatography (LC) with mass spectrometry (MS) or with nuclear magnetic resonance (NMR).

Detectors monitor the samples. Photometric detectors are based on UV/VIS (ultraviolet/visible) absorption, fluorescence or chemiluminescence. Photodiode array (PDA) and light scattering are other types of photometric detectors.

RI detects the difference between the refractive index of the sample and the reference. Electrochemical (EC) detectors measure concentrations.

3 SAMPLE PREPARATION AND DERIVATIZATION

3.1 Sample Preparation

Two techniques frequently used in sample preparation are solid-phase extraction (SPE) and supercritical fluid extraction (SFE). Another technique, LLE (liquid–liquid extraction), extracts compounds from an aqueous solution in a water-immiscible solvent. In SPE, analytes are absorbed and eluted according to their different affinities between the packing material and the mobile phase in a disposable column. On-line and off-line devices exist. In SFE, carbon dioxide is used to solubilize analytes. Important parameters are time and pressure.

3.2 Derivatization

Some molecules do not have UV (ultraviolet) absorbance characteristics, fluorescent or EC properties. Derivatization makes molecules detectable by adding a chromophore, fluorophore or electroactive product. Derivatization is done on-line or off-line. Precolumn derivatization is reaction before separation and postcolumn derivatization is reaction after separation.

4 NUTRIENT ANALYSIS

4.1 Amino Acids

Of the amino acids,1–3 9 are essential and 11 are nonessential. Some are conditionally essential or essential in specific circumstances. In Table 1 the essential and nonessential amino acids are listed. Nearly all foods contain amino acids either in the free form or as units in proteins. Reasons for detection are different and may be:

- demand for information of nutritive value,
- detection of adulteration in foods and beverages,
- detection of potentially toxic amino acids or peptides and
- measurement of meat protein content.

Sample preparation for a total amino acid analysis is performed by an acid or alkaline hydrolysis of the protein into amino acids. A commonly used hydrolysis is 6 M HCl at 110°C for 18–24 h. This procedure is a compromise for optimal estimation of a great number of amino acids. Alternatives could be: multiple hydrolysis times (24, 48, and 72 h), parallel application of several techniques, eliminating HCl using other organic acids, or using protective agents. An example of a problematic acid analysis is tryptophan. Sample preparation for tryptophan is hydrolysis in a base (e.g. NaOH) or enzymatic hydrolysis.

In many cases no sample pretreatment is necessary for a free amino acid analysis, only filtration and eventually dilution. Complete dissolution of the amino acids is pursued. For solid materials, homogenization of the sample and extraction in a solvent (e.g. 0.1 N HCl) are appropriate steps. An alternative is a hot acid aqueous extraction.

Large macromolecules, especially proteins, are responsible for loss of resolution over time. Deproteinization by precipitation with acids or organic acids, ultrafiltration, SPE with cation exchange or C18 resin, or guard columns with same packing as the analytical columns are steps in the sample cleanup. Precipitating agents are perchloric acid (PCA), phosphotungstic acid (PTA), picric acid (PA), trichloroacetic acid (TCA), acetonitrile (ACN), and sulfosalicylic acid (SSA).

PITC, phenylisothiocyanate; OPA, o-phthalaldehyde; FMOC, 9-fluorenymethyl chloroformate; AQC, 6-aminoquinolyl-N-hydroxysuccimidyl carbamate.

In Table 2 some derivatization methods are shown. The separation techniques of amino acids fall in different classes:

- Ion exchange chromatography (IEC): the majority of methods use cation exchange resins (sulfonated polystyrene). Many automated amino acid analyzers exist: LKB, Beckman, … Ninhydrin or OPA are used as postcolumn derivatizing agents.
- RP is now very popular: precolumn derivatization agents are PITC, OPA, FMOC, and AQC.
- Chiral: the number of enantiomeric separation methods of D- and L-stereoisomers of amino acids is growing. Some methods involve precolumn derivatization with a chiral reagent and separation with RPLC, and other separations of underivatized enantiomers on a chiral stationary phase or with chiral mobile-phase modifiers.

After separation, detection can be performed in the VIS (visible), UV or fluorescence mode.

4.2 Peptides

Peptides\(^{(4)}\) improve functional properties of food and can be used as antioxidants, antimicrobial agents, surfactants or to give characteristic flavors to foodstuffs.

Reasons of detection of peptides are:

- peptide mapping
- characterization of foods or
- characterization of bitter peptides.

Sample preparation consists of different steps:

- extraction by water, solutions of acetic acid or sodium chloride, or organic solvents and deproteinization by precipitation with the same acids as for amino acids or ultrafiltration,
- separation from peptides or sugars, organic acids, salts, etc. by anion- and cation-exchange resins or dialysis,
- separation of amino acids and peptides by IEC or SEC and
- a possible final step by passing through Sep-Pak™ C\(_{18}\) cartridges.

Separation is performed by RPLC, IEC or SEC. In RPLC, silica-based columns are most widely used. The mobile phase consists of a mixture of water and an organic solvent like ACN or methanol. Elution gradient and isocratic separations are performed. The pH is kept lower than three and ion pair forming agents may be added (e.g. trifluoroacetic acid, TFA).

In the ion-exchange mode two types of ion exchangers are used: cation exchangers for neutral and basic peptides and anion exchangers for neutral or acid peptides.

The material of size exclusion columns is silica, alumina or organic materials such as polyesters with OH groups.

UV, fluorescence and MS are used as detection modes. Derivatizing agents are used for enhanced detection such as dansyl chloride or PITC. Fluorescamine is a fluorescent derivatizing agent with an excitation peak at 390 nm and an emission band at 475 nm.

Many methods of separating stereoisomers have been published.

4.3 Proteins

Table 3 gives a summary of the classification of proteins of concern for the food analyst.

The reasons for detection vary:

- some proteins influence functional properties of food,
- cultivar discrimination,
- heat classification of skim milk powder or
- detection of rennet whey buttermilk solids in milk powder.

Proteins have to be solubilized by reduction agents (e.g. β-mercaptoethanol) before determination and the solution clarified by centrifugation or filtration to remove cell debris, lipids, and nucleic acids. Different classes of proteins can be separated by ultracentrifugation or

by selective precipitation using salts, organic solvents, or heat.

IEC, SEC, RPLC, hydrophobic interaction, metal chelate and bioaffinity, and hydroxyapatite chromatography are all possibilities for separating proteins. Metal chelate or bioaffinity chromatography is based on the affinity of a protein for a specific molecule in the stationary phase. Hydroxyapatite chromatography separates molecules on differential binding to phosphate and calcium sites of hydroxyapatite.

### 4.4 Lipids and Phospholipids

In Table 4 a simplified classification of lipids and phospholipids\(^{(5–7)}\) is shown.

- **Fatty acids:** fatty acids are the major part of acylglycerols and include saturated, mono-unsaturated and polyunsaturated fatty acids. Essential fatty acids, e.g. linoleic acid and \(\alpha\)-linolenic acid, are of great importance. Eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA), \(\omega\)-3-polyunsaturated fatty acids, possess health benefits.

- **Sterols and steryl esters:** phytosterols, as \(\beta\)-sitosterol, are found in groundnut and soybean oil. Cholesterol is associated with health problems.

- **Phospholipids:** phospholipids such as lecithin and products from soybeans are important in the food industry (e.g. emulsifiers). Sphingomyelin and phosphatidylinositol are other examples of phospholipids.

Lipids are extracted by solvents, centrifuged and filtrated, further washed and finally distilled or evaporated. Free fatty acids can be isolated from a lipid extract by SPE. Lipid classes can be separated by column chromatography, TLC (thin-layer chromatography) or HPLC.

Alternatives for the analysis of lipids by GC (gas chromatography) are HPLC RP and argentation-HPLC (silica gel with silver nitrate). Different detection modes are used: RI, UV, IR (infrared), ELSD (evaporative light-scattering detection), and CI (chemical ionization) MS.

For free fatty acids analysis GC is the method used traditionally. However, many HPLC methods have been used. Detection is neither sensitive nor selective. To increase these parameters UV or fluorescent derivatives are prepared either precolumn or postcolumn. Examples of derivatizing agents are 1-benzyl-3-\(p\)-tolu triazine, 1-\(p\) nitrobenzyl-3-tolu triazine, or 9-anthryldiazomethane (ADAM) and of derivatives are 2-naphthacylesters, phenacyl esters, and nitrophenylhydrazides.

Separation of \(cis\) and \(trans\) isomers of unsaturated fatty acids is performed by silver ion or argentation chromatography. Monohydroxy fatty acids are separated by NPLC and RPLC after derivatization with \(O-(p\)-nitrobenzyl)-\(N,N'\)-(diisopropyl)isourea (PNBDI). Many methods have been used to detect dimer and trimer acids, and higher molecular weight molecules formed during thermal oxidation.

Triglycerides can be separated by GC at higher temperatures (350 °C) or by RPLC. In the mobile phase no water is present (NARP, nonaqueous reversed-phase). An ion-exchange column impregnated with silver (silver IC) is also used.

Oxidized fats, caused by heat, light, and metals have undesirable favors and odors and result in health problems. Hydroperoxides and cyclic peroxides are such oxidation products. RPLC separation and ELSD or UV are possible methods to analyze these products.

Phospholipids are separated from other lipids by SPE. In the literature different compositions of solid or mobile phases are proposed. HPLC methods used for phospholipids can be arranged into separation techniques for phospholipid classes and separation techniques for molecular species. NPLC with a mobile phase of ACN, chloroform, or hexane/2-propanol is used to separate phospholipid classes. ELSD is mostly used as a detection system. UV-absorbing and fluorescent derivatization are applied in methods for molecular species characterization.

In the analysis of carbohydrates a difference is made between total soluble carbohydrates, total carbohydrates, reducing sugars and available carbohydrates. Among the many reasons for detecting sugars are the relationship that sugars have with health or health risks (e.g. dental caries), the determination of energy content and the need to determine adulteration. Other reasons are quality control of drinks and foodstuffs and monitoring of fermentation of alcoholic beverages.

Filtering or removing of proteins and fats by LLE, and extraction by (hot) water or solvents constitute steps in sample preparation. Dialysis is an alternative. The samples are further cleaned up by clarifying agents (e.g. Carrez reagents), solvent precipitation (e.g. mixture of acetate buffer/ACN), and ion-exchange or Sep-Pak™ cartridges (SPE). Precolumn or postcolumn derivatization can improve the detection of the analytes.

Often a RI detection follows separation over an amino-bonded silica, a special carbohydrate column or over an ion-exchange column. RI detection is the most widely used detection method for carbohydrates despite its low sensitivity. After a derivatization step, other possibilities are UV detection, EC detection, and evaporative light scattering detection.

4.6 Alcohols

Alcohols are detected in foods and beverages because knowledge of the alcohol content is needed to establish tax rates and because there may be adulteration by, for instance, glycerol, or methanol content which has toxic properties, and vinification processes and fermentation.

Sample preparation and cleanup of alcohols is carried out by distillation, solvent extraction, ion exchange, or by gel filtration. In most cases, however, samples are simply diluted and filtered through 0.45-µm or 0.2-µm filters. IEC is a possible choice. The used mobile phase is a diluted water solution of H₂SO₄ (0.004–0.001 N) or H₃PO₄. Detection is in RI, UV, or EC mode.

4.7 Vitamins

There are two groups of vitamins, fat-soluble and water-soluble vitamins. Table 6 shows the different vitamins, possible precursors or vitamin-related compounds.

Different reasons can be listed why vitamins are assayed in foods:
- to provide data about food composition,
- to check vitamin changes during processing, packaging, and storage,
- to evaluate geographical, environmental, and seasonal parameters,
- to monitor fortified foods for added quantities and
- to evaluate contract specifications and regulations.

</tbody>
</table>

Different HPLC methods are developed for the analysis of individual vitamins and vitamin-related products and for simultaneous determination of multiple vitamins.

4.7.1 Fat-soluble Vitamins

To extract fat-soluble vitamins from their matrices, and to remove glycerides, an alkaline hydrolysis (saponification) can be performed followed by LLE, enzymatic hydrolysis, alcoholysis, direct solvent extraction or SFE. Further cleanup is done by precipitation of sterols, open-column chromatography, SPE or SEC.

Separation modes are NPLC (vitamins A and E) or RPLC (carotenoids, vitamins D, E and K) or a combination of both modes (two-dimensional HPLC) for determining trace amounts of naturally occurring vitamins in foods. Absorbance of vitamins A, D, E and K and carotenoids or fluorescence of vitamin E are measured. An alternative is EC detection.

4.7.1.1 Vitamin A and Carotenoids Saponification or alkaline hydrolysis, hot or at ambient temperature, is used most to extract vitamin A and carotenoids. Many methods can be found in literature. Either NPLC or RPLC are used.

4.7.1.2 Vitamin D This vitamin can be extracted after saponification by a mixture of solvents. Vitamin D
absorbs in the 260-nm region. For trace amounts of vitamin D, and also vitamin K, separation is performed in a two-dimensional system.

4.7.1.3 Vitamin E Mostly NPLC but also RPLC are used for the determination of vitamin E. Sample preparation steps are hot saponification and solvent extraction. See Figure 1 for chromatograms of vitamin E.\(^{(10)}\)

4.7.1.4 Vitamin K NPLC, RPLC and two-dimensional methods are described in the literature.\(^{(9,11)}\)

4.7.2 Water-soluble Vitamins
Protein and nonprotein material is removed by enzymatic, acid or alkaline hydrolysis. TCA precipitates proteins. Finally water-soluble vitamins\(^{(11–13)}\) are extracted by LLE or SPE. In many cases, adequate protection from sunlight, higher temperatures and oxygen are necessary. Most analysts use RPLC.

UV, fluorescence or EC detection are preferred for vitamin C. Vitamin C, riboflavin, niacin, folacin, pantothenic acid and multivitamins are measured in UV mode. Fluorescence detection is used for vitamin C, thiamin, riboflavin and vitamin B\(_6\). Folacin can also be detected electrochemically.

4.7.2.1 Vitamin C HPLC is a very suitable analysis method for vitamin C. Methods using RP, polymer, ion exchange, ion exclusion, and amino columns and using UV, fluorescence, or EC detection are carried out.

4.7.2.2 Thiamin Thiamin is derivatized to thiochrome esters by ferricyanide to improve fluorescence detection. HPLC methods are frequently used to determine thiamine. An alternative is FIA (flow-injection analysis).

4.7.2.3 Riboflavin and Niacin Either acid or alkaline hydrolysis followed by an enzymatic hydrolysis can be used to extract vitamin B\(_2\) and B\(_3\) vitamers. RP or polymer-based columns are used to separate; UV or fluorescence are used to detect.

In Figure 2 a chromatogram is shown of folate standards.\(^{(14)}\)

4.8 Organic Acids

Organic acids in foods are the result of normal biochemical processes or by addition, hydrolysis or bacterial growth. They are added to foods as acidulants, stabilizers, or preservatives. They give a particular flavor, taste or aroma and are responsible for specific sensory properties. Table 7 gives a list of frequently found organic acids.

Beverages are simply diluted in an appropriate solution or in the mobile phase followed by centrifugation and filtration (0.45 or 0.22 µm). Carbonated drinks must be degassed. SPE or ion-exchange resins further clean up.

Sample preparation steps for solid samples are: extraction by mixtures of water and ethanol (70–80%) or ACN, centrifugation, and filtration. Pre- and post-column derivatization of organic acids is performed on-line or off-line. Derivatization methods for UV-detection use phenacyl, naphthacyl, and p-nitrobenzyl groups; for fluorometric detection 4-methyl-7-methoxycoumarin, 4-methyl-6,7-dimethylcoumarin, and 9-methylanthracine are used.

Organic acids are separated by IEC, RPLC or ion-exclusion chromatography. The method most used is ion-exclusion chromatography. In most methods UV, conductivity, or RI detection are used.

4.9 Organic Bases

Organic bases\(^{(15)}\) can be grouped by different criteria. In Table 8 different groups of organic bases are tabulated.

- Biogenic amines are naturally present in the central nervous system as neurotransmitters. They are often present in some foods such as cheese and fish and are reported to be responsible for several diseases when used in large amounts. Histamine is associated with scombroid poisoning. Biogenic amines can be formed by degradation processes in food.

</tbody>
</table>

- Unsulfonated aromatic amines: synthetic food colors contain toxic impurities or can degrade leading to carcinogenic aromatic amines.
- Mutagenic heterocyclic amines may be created by frying or boiling meat.
- Volatile aliphatic amines are responsible for organoleptic changes and capable of forming nitrosamines.
- Methylxanthines: caffeine and theobromine are present in cocoa, coffee, tea and many beverages. Caffeine can become a drug.
- Purines and pyrimidine bases are parameters for evaluating food quality or degradation.
- Cinchona alkaloids: quinine is a widely used drug and flavoring agent in beverages.
- Spicy food alkaloids: piperine, pipetine, and capsaicinoids are found in plants and used in cooking.
- Solanum alkaloids are compounds found in Solanum plants.
- Ergot alkaloids are produced by Claviceps fungi and may be poisonous.

Considering the wide variety of organic bases, all types of extraction, separation and detection methods are applied. A derivatization can be included in the method.

For biogenic amines and mutagenic heterocyclic amines RPLC is the most suitable method. Precolumn or post-column derivatization are used to enhance absorbance or fluorescence (e.g. AQC, FMOC, and OPA) of biogenic amines.

Frequently ion-pair chromatography or RPLC are used to analyze unsulfonated aromatic amines followed by spectrophotometric detection at 254 and ±510 nm.
RPLC and UV-detection at 254 nm are conditions of purine and pyrimidine analyses. A wide variety of methods exist for the separation of methylxanthines. Solanum alkaloids are separated by HPLC and UV in the 200 nm region; spicy food alkaloids are separated by HPLC and UV at 280 nm.

Most methods for ergot alkaloids consist of HPLC with fluorimetric detection.

4.10 Phenolic Compounds

In Table 9 a list of phenolic compounds is given.

Phenolic compounds are diverse compounds characterized by a hydroxyl group on a benzene ring. Phenolic compounds give the sensory quality, taste and flavor of fresh foods. They are useful for their pharmacological properties and in perfumery.

In sample preparation an extraction by organic solvents can be followed by an acid hydrolysis ($100^\circ\text{C} \cdot 2\text{~N~HCl} > 2\text{~h}$). Sample cleanup is by LLE, SPE or open column chromatography. Separation is done by RPLC followed by an UV or PDA (photodiode array) detection. The mobile phase is frequently a mixture of water, methanol or ACN, and an acid such as acetic acid or TFA. Often the mobile phase is buffered or an ion-pairing agent is added.

4.11 Bittering Substances

In Table 10 the different components of *Humulus lupulus* L. can be found.\(^{16}\)

$\alpha$- and $\beta$-acids are extracted by an organic solvent as toluene or methanol. Hop pellets or hop extracts are diluted in methanol or in the mobile phase. Ion-pairing or RPLC separate the components that are detected at 314 nm. Sample pretreatment of iso-$\alpha$-acids consists of precipitation, LLE and SPE. Separation is in the ion-pairing mode and detection at 270 nm.

4.12 Pigments

In Table 11 the different pigments are tabulated.

- Carotenoids are detected in foodstuffs to evaluate food quality by pigment concentration, to meet regulations on colorants and because of the interest in carotenoids as provitamins and antioxidants. In sample preparation UV-light and heat should be avoided. After solvent extraction lipids and chlorophylls are removed by saponification. Sterols can be removed by precipitating them in different solvents. Carotenoids are separated by either NPLC or RPLC. Detection is in UV/VIS mode or also with MS.
- Chlorophylls: the green color of chlorophyll gives an idea of the degreening or maturing of fruits, of food quality or of color loss during processing. Chlorophylls are possibly natural colorants. All sample preparation and analysis steps must be carried out in darkness. After solvent extraction, filtering and SPE, chlorophylls are separated by NPLC but preferably by RPLC. Detection is by absorbance or fluorescence.
- Anthocyanins: the reasons for detecting anthocyanins in food are the same as for carotenoids and chlorophylls – evaluation of food quality by color and the use of natural colorants. Extraction is done by acid solvent mixtures. Further cleanup is worked out by SPE. A very good choice is RPLC for separation and UV/VIS or PDA for detection.
- Betalains: once again the reasons for detection are identical. Betalains are extracted in water or water–solvent mixtures. Further cleanup has to be

\(^{16}\)
done by chromatographic methods. Good separation methods are RPLC or ion-pairing. Detection is in UV/VIS mode.

- Myoglobin gives the color to meat. This is the prominent reason for detection: meat quality. Myoglobin is extracted in water or aqueous buffers. Samples are further cleaned up by fractionating with ammonium sulfate, dialysis, or column chromatography. Almost all modes of LC have been used to analyze myoglobins.

5 RESIDUES

5.1 Mycotoxins

Mycotoxins\(^{17}\) are fungal metabolites that can be found in foods, especially grains, peanuts and milk. Contamination can occur before and in all steps of food production: in the growing crop, during storage and processing and in the finished food. Mycotoxins are dangerous for human health and may be carcinogens. The different mycotoxins are enumerated in Table 12.

Mycotoxin distribution in raw materials is seldom homogeneous. Good attention must be given to the sampling. After solvent extraction, cleanup is worked out by filtration, liquid–liquid partition, column chromatography and SPE. A precolumn derivatization (e.g. TFA) or postcolumn derivatization (e.g. iodine) step can be included. A good alternative for HPLC as an analysis technique is TLC.

Aflatoxins are extracted with chloroform, methanol, acetone, or ACN. The samples are cleaned up by SPE or immunoaffinity (IA) columns. Separation is in RP mode followed by fluorometric detection.

Extraction of Ochratoxin A is with organic solvents in acid medium followed by SPE or IA cleanup. The separation in RP mode is also followed by a fluorometric detection. GC not HPLC is the most used separation technique for trichothecenes. Determination of zearalenone is performed by RPLC and fluorescence detection.

5.2 Residual Antibacterials

Residues of antibacterials\(^{18}\) are found in dairy products in low concentrations. Consequences of residues in foods are antibiotic resistance, mutagenic and carcinogenic effects. In Table 13 different classes of antibacterials with a few examples can be found.

Owing to the wide variety of compounds, sample preparation methods are very different. The methods include extraction, cleanup (SPE) and if necessary derivatization.

RPLC is an excellent technique for separating residual antibacterials. Detection is in different modes.

5.3 Residues of Growth Promoters

Growth promoters\(^{19}\) are used for therapeutic or prophylactic purposes and for a better breeding efficiency or better protein conversion. The European Union has prohibited substances which have a hormonal action (some hormones may be used for therapeutic purposes).

A classification is shown in Table 14.

Sample preparation consists of a simple homogenization followed by centrifugation or enzymatic digestion followed by extraction by organic solvents. Further cleanup is performed by column chromatography, SPE.

or MSPD (matrix solid-phase dispersion). HPLC can be used to separate the residues in different columns (NPLC, RPLC and other). Detection is UV, fluorescence or EC detection.

### 5.4 Pesticides

Pesticides are chemical compounds that are used to control pests. Dependent on the pest, acaricides, fungicides, herbicides, insecticides, etc. are used. More than 1300 pesticides are available. The major groups are summarized in Table 15.

Residues of pesticides in food can have different negative effects on human health. The extraction modes for pesticide residues are SPE, solvent extraction and SFE. Further cleanup methods are liquid–liquid partitioning and distillation. If necessary, precolumn derivatization is performed (e.g. using p-nitrobenzylchloride – an UV derivatizing agent for ETU (ethylenethiourea), a degradation product of ethylene-bis-dithiocarbamate) or postcolumn derivatization (e.g. using OPA, a fluorescent derivatizing agent of N-methylcarbamate).

Considering the large number of pesticides and the wide variety, most types of columns are used: NPLC, RPLC, IEC, amino-bonded, diol-bonded, cyan bonded and SEC. Also all types of detection system are chosen in one or another method: UV, fluorescence or EC.

#### 5.4.1 Fungicide Residues

Fungicides have a wide variety of chemical structures and functional groups and are nearly all multifunctional. In Table 16 fungicides are classified into six categories.

Multiresidues of fungicides are extracted by solvent extraction (ACN or acetone) and further cleaned up by LLE, column chromatography, SPE and others. Samples can be analyzed by RPLC or ion-pairing LC.

#### 5.4.2 Herbicide Residues

The major classes of herbicides can be found in Table 17. The same extraction procedures and cleanup methods as for organophosphates, organochlorine pesticides and

fungicides are applicable. In some cases precolumn or postcolumn derivatization to enhance UV or fluorescence detection is carried out. All types of columns are used to separate the residues. Detection is in UV or fluorescence modes.

5.5 N-Nitroso Compounds

Table 18 shows a classification of NOCs (N-nitroso compounds).

NOCs have the functional group N=N=O. They are formed by the reaction between a nitrogen-containing organic compound (amines, amides) and a nitrosating agent (nitrites, nitrogen oxide gases). NOCs are mutagenic, carcinogenic and teratogenic. The best known NOC is N-nitrosodimethylamine (NDMA).

Sample preparation has different steps: extraction, cleanup and concentration. Extraction is performed by solvent extraction, steam or vacuum distillation or SPE. Cleanup is achieved by LLE or column extraction. Because many NOCs are nonvolatile or are not separated by GC, HPLC is a good choice. Different approaches are carried out:

- HPLC methods with postcolumn NO detection by chemiluminescence (HPLC/TEA, thermal energy analysis). The stationary phase is silica, phenyl-bonded, cyano-bonded or amino-bonded silica.
- HPLC methods with UV detection of postcolumn or precolumn dinitrosation products other than NO on a RP column.

6 MISCELLANEOUS

6.1 Colorants

Natural (from vegetable, animal or mineral origin) or synthetic (organic or inorganic) colorants are used to provide foods with an attractive appearance. Classification of colorants is not simple but such a classification has been carried out by EEC, International Numbering System, and in the Color Index. Applied colors are erythrosine, amaranth, Ponceau 4R, Allura Red, Sunset Yellow, and tartrazine.

Use of dyes or chemical impurities in colorants can have undesirable side effects. Azo dyes are reduced to aromatic amines. Metals, aromatic amines and others are detected as impurities.

Liquid samples are filtered through 0.45-µm filters and injected. Water-soluble samples are dissolved in (heated) water. Solid foods are extracted in organic solvents such as methanol or petroleum ether, filtered or centrifuged.

Concentration techniques for dyes are wool-dyeing procedures, column chromatography, IEC, ion-pair chromatography, solvent extraction, or SPE.

Food colorants can be separated by NPLC, ion-pair chromatography, or RPLC combined with UV-detection.

6.2 Preservatives

Preservatives are chemical compounds added to food products to prevent or inhibit the activity and growth of microorganisms. Sulfites and sulfur-based compounds are detected by ion-pair HPLC. In most cases the detection is in the EC mode.

Post-harvest preservatives, thiabendazole, biphenyl and o-phenyl phenol, used to protect certain fruits, are extracted by ethyl acetate, separated (NPLC/RPLC) and UV detected.

The organic acids formic acid, benzoic acid, sorbic acid and esters or salts of 4-hydroxybenzoic acid are extracted from the matrix by steam distillation or direct extraction. Separation is carried out in normal-phase, RP, ion-pair, ion-exchange or amino-bonded phase. Detection is at 235 nm.

6.3 Synthetic Antioxidants

Synthetic antioxidants inhibit the process of oxidation in foods. Only the primary antioxidants alkyl gallates, butylated hydroxyanisole (BHA), butylated hydroxytoluene (BHT), tert-butylhydroquinone, nordihydroguaiaretic acid, and ethoxiquin are discussed here.

The last three are not generally allowed in foods or have toxic effects.

Vacuum or steam distillation are frequently used for isolation of antioxidants from food samples. HPLC is not the only method used to analyze antioxidants. NPLC, RPLC (the majority), SEC and IEC are performed. In most methods discussed, 280 nm is the chosen wavelength.
6.4 Sweeteners

The capacity to produce a sweet taste is inherent in sugars such as sucrose, amino acids like aspartame, proteins such as thaumatin and cyclic (cyclamates) and aromatic organic derivatives (neohesperidin dihydrochalcone).

Some intense sweeteners are extracted from plants (glycyrrhizin, steviosides, thaumatin), others are obtained by organic synthesis (acesulfam-K, sucralose, saccharin). Most of the intense sweeteners are not metabolized by the body.

Bulk sweeteners (simple sugars, sugar alcohols, and starch) are mostly metabolized by the body. Intense sweeteners are nonnutritive or noncaloric sweeteners. Their sweetness is 30 to 3000 times that of sucrose.

- Acesulfam-K is very stable even at high temperatures. HPLC is a very good choice to determine Acesulfam-K in foods. Generally a RP column and a mobile phase consisting of ACN and KH2PO4 buffer are used. The sweetener and other compounds (aspartame, saccharin, ...) are detected by UV in the region of 200–230 nm.

- Aspartame: the stability of aspartame in dry products is relatively good. Decomposition occurs in liquid products at higher temperatures and at pH <3.0 or >6.0. A breakdown product is phenylalanine which is inconvenient for individuals suffering from phenylketonuria.

A very suitable analysis method is RPLC. UV-detection is between 210 and 220 nm. By varying the organic modifier or the pH different of the mobile phase sweeteners, decomposition products or other molecules can be detected simultaneously.

- Cyclamate: Stability of cyclamate in foods is very good over a wide range of parameters. Cyclamate is separated from other components by HPLC. Precolumn (e.g. sodium hypochlorite) or postcolumn derivatization (e.g. methyl violet) has to be done.

- Glycyrrhizin (extract from Glycyrrhiza glabra L.) is analyzed on a RP column using ACN–acetic acid–water as a mobile phase and a detector at 254 nm.

- Saccharin is commonly used in different types of food. HPLC is a very good choice for determining saccharin. The chromatographic conditions are the same as for acesulfam-K.

- Stevioside is a glycoside found in the leaves of Stevia rebaudiana Bertoni. HPLC conditions are
  - RP or amino-bonded phase column,
  - ACN–water or methanol–5 mM NaOH as mobile phase,
  - detection at 210 nm.

7 ANIONS AND CATIONS

Important anions and cations and reasons for their detection are tabulated in Table 19.

In sample preparation of anions the following steps can be distinguished: dilution, filtration, precipitation of proteins (treating with Carrez solutions), and SPE. Steps in the sample cleanup of cations are grinding, dilution and filtration.

Separation modes for anions and cations are IEC or ion-exclusion chromatography. Conductivity detection is common in IC. However, eluents and analyte are conductive and thus it is difficult to distinguish the difference in conductivity between analyte and eluent. A suppression system reduces the conductivity of the eluent: suppression IC. In nonsuppressed IC low ionic strength eluents are used. Indirect detection with the help of a counterion is in the UV/VIS region. CZE (capillary zone electrophoresis) is a good alternative.

Near-infrared Spectroscopy in Food Analysis

Brian G. Osborne
BRI Australia Ltd, North Ryde, Australia

1 Introduction

Near-infrared (NIR) spectroscopy is based on the absorption of electromagnetic radiation at wavelengths in the range 780–2500 nm. NIR spectra of foods comprise broad bands arising from overlapping absorptions corresponding mainly to overtones and combinations of vibrational modes involving C–H, O–H and N–H chemical bonds. The concentrations of constituents such as water, protein, fat and carbohydrate can in principle be determined using classical absorption spectroscopy. However, for most food samples, this chemical information is obscured by changes in the spectra caused by physical properties such as the particle size of powders. This means that NIR spectroscopy becomes a secondary method requiring calibration against a reference method for the constituent of interest. As a consequence of the physics of diffuse transmittance and reflectance and the complexity of the spectra, calibration is normally carried out using multivariate mathematics (chemometrics).

NIR spectroscopy is used routinely for the compositional, functional and sensory analysis of food ingredients, process intermediates and final products. The major advantage of NIR is that usually no sample preparation is necessary, hence the analysis is very simple and very fast (between 15 and 90 s) and can be carried out on-line. One of the strengths of NIR technology is that it allows several constituents to be measured concurrently. In addition, for each fundamental vibration there exists a corresponding series of overtone and combination bands with each successive overtone band approximately an order of magnitude less intense than the preceding one. This provides a built-in dilution series which allows several choices of absorptions of different intensity containing the same chemical information. Finally, the relatively weak absorption due to water enables high-moisture foods to be analyzed.

The major limitation of NIR spectroscopy in food analysis is its dependence on less-precise reference methods.

1 INTRODUCTION

The NIR forms that part of the electromagnetic spectrum in the wavelength range 780 nm to 2500 nm (Figure 1). NIR, like all radiation, behaves as a wave with the properties of simple harmonic motion which may be defined in terms of two properties:

- the frequency of vibration
  \[ \text{frequency} = \text{no. of times the wave pattern is repeated in 1 s} \]
  \[ \text{angular velocity}/2 \]

- the wavelength
  \[ \text{wavelength} = \frac{\text{velocity of light}}{\text{frequency}} \]

Chemical bonds between atoms in molecules vibrate and to a first approximation this vibration behaves as a simple harmonic motion. The motion of each atom may be treated as an independent vibration with respect to a fixed centre of mass of the molecule rather like a mass attached to a spring. The vibration frequency is a function of the masses of the two atoms \( m_1 \) and \( m_2 \) and the strength of the bond \( k \) and there is a parabolic relationship between potential energy and interatomic distance.
Figure 1 Principal types of NIR absorption bands and their locations.

Figure 2 A typical spectrum of a powdered cereal sample (upper curve) and some of its constituent absorptions.

When the frequency of the radiation matches that of the vibrating molecule, there will be a net transfer of energy from the radiation to the molecule which can be measured as a plot of energy versus wavelength called a spectrum (Figure 2). However, energy is not transferred continuously but in discrete packets called quanta. In consequence, molecules can only occupy discrete energy levels defined by whole numbers $0, 1, 2, \ldots$ and the energy change required for a transition between two levels is directly related to the frequency of the energy by multiplying by $\hbar$ (Planck’s constant). For simple harmonic motion, the absorption or emission of energy can only take place if it matches a transition between any pair of adjacent energy levels. Since almost all the molecules in a sample will normally occupy the lowest energy level 0, this means that the only possible transition is from 0 to 1, called the fundamental.

The simple harmonic model does not adequately describe the vibrational motion of chemical bonds because at one extreme atoms repel one another the closer they approach and at the other extreme the molecule dissociates. For this more realistic model, transitions from energy level 0 to 2, 0 to 3 etc. become possible and these are referred to as first, second etc. overtones with frequencies corresponding approximately to twice, three times etc. that of the fundamental. The frequencies of many overtone bands are in the NIR region. The greater the deviation of a particular bond system from harmonicity, the greater the intensity of overtone bands and the most anharmonic bonds are those involving the lightest atom, hydrogen, and a heavier atom such as carbon, nitrogen or oxygen.

While each frequency of vibration of a complex molecule generally involves oscillation of all the atoms, those atoms undergoing large amplitude motions are often limited to a particular functional group, e.g. $\text{–OH, –NH}_2$ etc. The characteristic frequency is similar for the same functional group where it appears in different molecules. This concept of characteristic group frequencies is the basis of analysis by infrared (IR) and, because each fundamental will be associated with its own potential energy curve and its own set of overtones, of analysis by NIR also.

The number of bands a given molecule will produce can be calculated from the number of coordinates required to describe the total momentum of the molecule, $3n$ coordinates describe the location in space of a molecule of $n$ atoms of which 3 describe the translational and 3 the vibrational motion (2 if linear) of the molecule. There are therefore $3n - 6$ ($3n - 5$ if linear) possible modes of vibration but some of these may be the same. Furthermore, absorption can only occur if the molecular vibration is accompanied by a change in dipole moment such as with the hydrogen chloride molecule.

Another type of absorption band occurs in the NIR region. Combination bands arise by interaction of two or more vibrations taking place simultaneously and the frequency of a combination band is simply the sum of multiples of the relevant fundamental frequencies. Thus, a triatomic molecule with 3 fundamental bands could have 3 first overtones, 3 second overtones etc. and 6 combination bands. It soon becomes obvious that NIR spectra are much more complex than IR spectra. Nevertheless, overtones and combinations can still be assigned to group frequencies.

2 INSTRUMENTATION

Successful application of NIR depends on the correct choice of instrument. There are three different types available (described in detail by Osborne et al.\textsuperscript{(1)})
2.1 Monochromators
Grating monochromators are used to measure the full visible and NIR spectrum and may be used in transmittance or reflectance mode. They are therefore the most versatile instruments. Monochromators are generally used for research or when a wide range of different applications is required. Three different detectors are available: a silicon detector covers the range 400–1100 nm, an indium gallium arsenide covers the range 800–1700 nm and a lead sulfide the range 1100–2500 nm. Some instruments contain both silicon and lead sulfide detectors (giving them a wavelength range 400–2500 nm), some only the lead sulfide. The latter would be restricted to measurement of powdered or granular samples by diffuse reflectance (see section 3.2) or transmittance via fiber-optic probes. At least one model of NIR monochromator has been designed for on-line use via either fiber-optics or a powder sampler.

Another type of dispersive monochromator used in NIR instruments is the acousto-optically tunable filter (AOTF). An AOTF comprises a crystal of TeO₂ through which a plane travelling acoustic wave is generated at right angles to the incident light beam. This causes the crystal to behave as a longitudinal diffraction grating with a periodicity equal to the wavelength of sound across the material. The main advantages of AOTF over grating instruments is their mechanical simplicity (i.e. no moving parts) and their wavelength stability.

2.2 Diode Array Spectrometers
Diode array spectrometers employ an array of IR-emitting diodes. These function as both the light source and the wavelength selection system. Diode array instruments typically cover the range 400–1700 nm. They have the advantages that the measurement is very fast (e.g. one spectrum per second) and noninvasive. These features are particularly useful where a high sample throughput or ultra-rapid on-line measurements are required.

2.3 Filter Instruments
The simplest and cheapest NIR instruments are based on a limited number, usually between six and twenty, of interference filters. These filters are chosen to represent the absorptions used for the most popular applications, e.g. protein, moisture and oil in agricultural samples. Filter instruments are designed for a limited range of routine analyses, either in the laboratory or on-line.

3 SAMPLE PRESENTATION
The wide range of applications of NIR in food analysis is possible because of the different sample presentation techniques. There is a technique available for any type of liquid, slurry, powdered or solid sample.

3.1 Diffuse Transmittance
Radiation interacting with a sample may be absorbed, transmitted or reflected. In the classical spectroscopy experiment, reflection is eliminated so that the proportion of radiation attenuated by the sample may be measured as transmittance. Beer’s law then defines a proportionality between transmittance and the product of concentration of the absorbing species and path length. For a clear transparent liquid sample such as beer, hot starch melts, wine or vegetable oil, the path length may be fixed by means of a static or flow-through sample cuvette or a pair of fiber-optic probes and a calibration developed using samples of known concentrations. For example, Halsey used standard solutions of ethanol in water to develop a calibration for alcohol content of beer. It should be noted that, owing to the relatively weak intensities of NIR absorption bands, samples such as vegetable oils may be analyzed without dilution in a solvent. Beer’s law is only valid in the absence of light scatter in the sample. Scattering changes the path length through which the radiation passes and, because the amount of scattering varies from sample to sample, the path length cannot be defined. This type of experiment is known as diffuse transmittance (Figure 3), the most well-known example of which is liquid whole milk. The fat globules in the milk scatter light in the manner shown and invalidate Beer’s law. Diffuse transmittance measurements are usually carried out in the 800–1100 nm region of the spectrum where the weak absorptions enable useful data to be obtained using thicknesses of 1–2 cm of samples such as meat, cheese or whole grain. Near-infrared transmittance (NIT) instruments are particularly applicable to the analysis of whole grains and a typical apparatus is shown schematically in Figure 4. A sample of grain is placed in a hopper from where aliquots are dispensed into the measurement chamber. When analysis is complete, the sample is discharged into a collection tray. This arrangement lends itself well to adaptation for on-line measurements (see section 5.1).

Figure 3 Diffuse transmittance spectroscopy.
3.2 Diffuse Reflectance

For a smooth surface such as glass, most of the radiation is reflected from the surface by regular or specular reflection and no absorption takes place. In the 1100–2500 nm region, the amount of scattering makes the path length so great that transmittance through 1 cm of most samples is negligible. This situation is called diffuse reflectance because most of the incident radiation is reflected. If a matt surface reflects diffusely without penetration into the sample, like specular reflectance no absorption takes place. If, however, some of the radiation penetrates the surface when it reaches each particle it can be reflected, absorbed or transmitted. The net result is that the diffusely reflected radiation ($R$) can be empirically related to concentration ($c$) in an analogous way to Beer's law i.e. $\log 1/R = kc$ where $k$ is a factor which incorporates both absorptivity and path length.

A typical NIR diffuse reflectance experiment is shown in Figure 5. A powdered sample such as wheat meal is packed into a 1 cm-deep sample cell and covered with a quartz window. The sample cell is then placed into the instrument where it is illuminated with NIR radiation and the reflected radiation measured by either a set of detectors set at 45° to the incident beam or a single detector onto which the radiation is focused by means of an integrating sphere. This configuration has been adapted for on-line measurement using a powder sampler for flour or milk powders.

The diffuse reflectance experiment can be adapted for use with liquids by placing a ceramic tile beneath the sample. In this sample presentation mode, known as transfectance, the radiation is transmitted through the sample, reflected from the ceramic then transmitted back through the sample before finally reaching the detector. Transfectance is thus a hybrid of transmittance and reflectance. Interactance, another hybrid of transmittance and reflectance, involves illumination and detection at laterally separated points on the sample’s surface. It is normally accomplished using a fiber-optic probe in which one set of fiber-optic bundles carries the incident radiation and another carries the reflected radiation. This type of arrangement is particularly useful for large samples such as intact fruit.

3.3 On-line Samplers

Ideally, a sensor needs to be sufficiently compact and robust to be placed in the required position on-line. It needs to be relatively low cost, rapid and capable of measuring the desired analyte or property on an intact sample. Finally, it must be capable of accurate and stable calibration. NIR instruments meet these requirements. Since the applications are limited and predefined, filter instruments which fulfil the criteria of compactness, robustness and cost can usually be employed. NIR is inherently a rapid technique (as fast as one spectrum per second with diode array technology) and data from many measurements can be combined into a moving average so as to identify trends.

There are three types of NIR on-line analyzer.

3.3.1 Remote (Noncontact) Sensor

The first dedicated on-line NIR sensor was invented by Edgar and Hindle of Infrared Engineering Co in the UK. This is based on a sensing head, which is referred to as a “gauge”, remote from the sample. This design has the advantages of a low cost of instrument and simplicity of installation but imposes severe constraints on instrument design as it is susceptible to interference from ambient light variations, dust build-up on the optical surfaces and atmospheric humidity variation. The Infrared Engineering gauge was therefore designed specifically for on-line application and constructed to
minimize such potential interferences. The Infrared Engineering MM55 Gauge is based on a non-contacting sensing head fixed approximately 200 mm from the product flow by mounting to the side of a section of spouting inclined at an angle of 60° from the horizontal. The gauge focuses light from a quartz halogen lamp into a parallel beam which is projected onto the product via a filter wheel which transmits narrow bands of energy at the desired NIR wavelengths. The reflected energy, which has been modulated by interaction with the product, is captured by a detector in the gauge. In this way, measurements on the moving flour stream are taken through a toughened glass window at a rate of up to five per second. Signals from the MM55 gauge are conveyed to an electronic processing unit which contains the calibration equation and produces the analytical result. This is passed to a strip recorder to provide a permanent record. Applications of the MM55 in the food industry include moisture determination on both continuous and discontinuous samples such as powders and discontinuous samples such as whole biscuits, control of protein in flour, monitoring of fat content of potato crisps and sorting of fruit.

Recently, in Australia, a novel application of NIR spectroscopy to the monitoring of bread dough development has been invented by Wesley et al. The invention makes use of the high scan speed (one spectrum per second) of the Perten DA-7000 diode array instrument. In this case, the instrument was inverted over an open mixing bowl and the signal from the dough was recorded continuously without stopping the mixer. In this way, using second derivative data at defined wavelengths assigned to protein and water, an NIR mixing curve was obtained. The NIR mixing curves were in good agreement with curves obtained using measurement of mixer torque over a range of flour types and mixer conditions.

3.3.2 By-pass Sampler

To control the composition of the grist (wheat mixture) during the blending process, it is necessary to perform measurements on the grain itself because the time delay between blending the wheats and producing the final flour is too long for an effective feedback control loop. Whole grain NIR instruments generally employ a hopper and flow-through cell and are thus relatively easy to adapt to on-line use. An on-line version of the Infratec 1225 Whole Grain Analyzer is commercially available.

One of the first near-infrared on-line powder samplers (NIROS) was based on an InfraAlyzer 300B instrument which was split into two parts comprising the electronics unit which would be removed from the immediate vicinity of sampling and the optical unit which was to be modified for on-line sample presentation. This method of sample presentation was selected on the principle that the sample needed to be held stationary against the optics window during the measurement cycle and that the flour surface should be smooth, continuous and firmed under pressure. These conditions were met by taking direct samples from the flour stream, either from gravity-fed spouting or a positive pressure blowline, into a mechanism designed to reproduce the action of a human operator in packing flour into a sample cup.

NIR on-line samplers were first developed to measure the protein content of flour. This is still the most popular application and provides an excellent example of an NIR feedback control system. Dried gluten is commonly used, particularly in Europe, to replace wholly or partly the protein in flour which would otherwise be derived from high-protein wheat in the grist. The success of on-line NIR for monitoring flour protein content therefore led to its incorporation into a closed-loop control system for gluten addition to flour. A mixing screw is installed between the gluten feed and the NIR sampler station from which a feedback signal controls the gluten feeder. The system has proved to be an efficient and accurate method of control of gluten addition to achieve a target protein content in the flour.

3.3.3 Fiber-optic Probe

Fiber-optic probes have the widest range of applications in on-line food analysis. Uses include dairy products, meat, fruit, beer and extruded snack foods.

Extrusion cooking is used to manufacture a wide range of products from cereals, including breakfast cereals, snack foods and pet foods. In these products, texture and density are key quality requirements which are controlled by the processing conditions summarized by the term “degree of cook”. Conventionally, control is attempted by measurement of inputs such as the moisture content, screw speed, barrel temperature, etc. on the basis that the relationship between these and the product quality is understood. However, a more direct means of control is highly desirable. In contrast to breadmaking, where the product structure is largely controlled by protein development, in extrusion cooking it is the starch component of the cereal-based raw material which is the chief functional ingredient. Therefore, the aim was to use NIR to monitor changes in starch structure. Initially, products were prepared over a wide range of processing conditions and the extrudates freeze-dried and ground to powders prior to NIR spectroscopy. Since successful calibrations based on spectral features related to starch structure were obtained using the powdered samples, the measurement was attempted on-line. A fiber-optic reflectance probe was installed in the die of the extruder and the light was transmitted through the melt and reflected back from a polished steel pillar;
in effect, therefore, a transfectance measurement was used. The spectral characteristics of the different forms of starch found in the hot melts close to the die of the extruder were identical to those of the powdered extrudates. This research has opened the way to an on-line process monitoring and control system for extrusion cooking.

4 CALIBRATION DEVELOPMENT

In NIR analysis, the calibration provides all three basic functions of analytical chemistry i.e. separation, identification and quantification. Therefore, derivation of the calibration equation for each application is the most crucial step in reliable and accurate analysis. There is, however, no unique method for deriving satisfactory calibration equations. The following sections provide an overview of the main techniques used and more detail can be found in Osborne et al.(1)

4.1 Data Preprocessing

Quantitatively the most important factor in the NIR reflectance spectrum is the particle size of the sample. Log(1/R) increases with increasing particle size because the apparent path length becomes longer. Therefore, for example, the same wheat sample ground to different particle sizes will result in substantially different spectra. However, the effect is not additive but multiplicative, i.e. proportional to log(1/R). Since in reflectance spectra of foods and agricultural materials log(1/R) coincidentally increases with increasing wavelength, the effect of particle size appears to be a function of wavelength.(6,7)

Correction for particle size is accomplished empirically by multiple regression mathematics but many spectroscopists prefer to use derivatives. The first derivative

$$\frac{d(\log 1/R)}{d\lambda}$$

is the slope of the spectrum at wavelength \( \lambda \) and is calculated as the difference between log 1/R at two adjacent wavelengths or, more usually, two segments in which the data are smoothed (averaged) over a small region of the spectrum defined by the segment size. The difference between these wavelengths or segments is called the gap. The second derivative

$$\frac{d^2(\log 1/R)}{d\lambda^2}$$

is the difference between two adjacent first derivatives. Derivative mathematics is described using the notation (derivative order, gap, segment, second smoothing) e.g. (2, 8, 8, 1) means a second derivative with a 16 nm gap and 16 nm segment.

Derivatives have two useful properties:

1. resolution of overlapping bands;
2. deconvolution of background (derivative ratios$^6$ correct for multiplicative effects).

The effect of particle size can also be overcome by multiplicative scatter correction$^8$ or standard normal variate and detrend.$^9$ The multiplicative scatter correction algorithm proceeds by computing the mean spectrum of the sample set and rotating each sample spectrum so that a regression line drawn through it aligns with a regression line drawn through the mean spectrum.

4.2 Sample Population Structuring

The NIR analysis of food and agricultural samples is based on calibration against a reference method using a set of samples which represent all the variability in the population from which they are drawn. The problem becomes one of identifying these samples. One set of criteria would be to obtain analytical data on a large database of samples and select those with the most variation in composition. However, this is an expensive option. The concept of population structuring was introduced by Shenk and Westerhaus.$^{10}$ The idea is to assemble a library containing the NIR spectra of a large number of samples and use discriminant analysis techniques to define the boundaries of the library. The spectra of further samples can then be examined to ascertain whether they belong to the population represented by the library and whether their spectra are different to those of existing samples. The spectral library can be used in several ways:

- to define the optimum calibration set;
- to verify that test samples match the calibration;
- to produce locally weighted calibrations for optimum measurement accuracy;
- to identify new samples with which to extend the calibration.

4.3 Regression Techniques

The usual method of calibration of NIR instruments is by multiple linear regression of the reference data on the spectral data. The difficulty in this is twofold. Firstly, NIR spectra contain a large amount of data whereas only a few terms should be included in a regression equation. Secondly, because of the effect of scatter, the raw NIR data are highly intercorrelated and this precludes the use of forward stepwise regression, the most common method of selection of terms in
NEAR-INFRARED SPECTROSCOPY IN FOOD ANALYSIS

For fixed filter instruments, the wavelengths for each application may be known. If not, there are only a few from which to select and is feasible to employ an all possible combinations strategy. For monochromator or diode array instruments on the other hand, more sophisticated methods are necessary. The use of mathematical pretreatments such as derivatives or multiplicative scatter correction (see section 4.1) would make forward stepwise selection more reliable but it is important to ensure that the selected wavelengths are consistent with known chemical absorptions. This can be done by comparing a plot of correlation versus wavelengths (Figure 6) with the spectrum of the constituent of interest. However, this is not always possible. For example, functional properties do not usually have a defined spectral pattern. An increasingly popular approach, therefore, is to reduce the amount of data by principal components analysis then perform linear regression on the principal components.

If the principal components are selected with regard to minimizing the correlation coefficient, the method becomes partial least squares (PLS). The end result is a calibration equation from which the constituent of interest may be calculated from a (usually) linear combination of spectral data. The equation has associated statistics which define the closeness of fit of the actual and predicted values to the least squares line. It is always important to plot a scatter graph as illustrated in Figure 7 in order to detect any aberrant data. Ideally, the scatter plot should contain data points distributed evenly about the line but within the confidence limits as shown in the example.

4.4 Qualitative Analysis

In applications such as authenticity testing (see section 5.8), where the aim is to classify rather than perform a quantitative determination, a qualitative or discriminant analysis approach is often used. The mathematical approach to this problem is to develop a model which defines the mean and standard deviation of each sample type in multidimensional space then test to which group an unknown sample belongs. This test is based on a non-Euclidean distance measurement such as the Mahalanobis distance. The Mahalanobis distance is defined according to elliptical contours spreading out from the group centres. The mathematics and applications of discriminant analysis are described by Mark. More sophisticated classification models have been achieved using artificial neural networks (ANNs). ANNs consist of input nodes which receive one piece of spectral data each and distribute it to a hidden layer of nodes where the data are transformed before being distributed again to a set of output nodes. The nodes simply provide the mechanism for distribution of the data through the hidden layer which may be considered a nonlinear function approximation machine. The crucial feature of ANNs is that they are adaptive. One example of the application of ANNs to a food classification problem has been published by Hervas et al.

5 FOOD APPLICATIONS

5.1 Cereals and Cereal Products

NIR has been used for the quality testing of crossbred material from wheat breeding programs since the late 1970s. Because NIR is rapid, low cost per test and requires a relatively small quantity of sample, it is routinely used throughout the world to determine the protein content.
of wheat to allow breeders to screen large numbers of lines for this key characteristic. In addition, NIR is widely used to replace some of the chemical tests necessary as part of a quality testing program (Table 1). In particular, NIR hardness and moisture measurements may be used to determine the conditioning requirements prior to test milling while protein and moisture may be determined on the resulting flour.

The ultimate application of NIR analysis in a wheat breeding program would be direct prediction of functional quality including flour yield, damaged starch, water absorption, dough development time, extensibility and loaf volume. Although some breeding programs are using NIR to eliminate lines according to some of these measurements, they have not gained widespread acceptance. The reason appears to lie in the sensitivity of calibration to changes in variety, growing location and season, which necessitates frequent re-calibration. The availability to breeding programs of whole grain instruments provides a renewed incentive to develop the use of NIR to take the place of the entire procedure for quality screening of early generation lines where the numbers and quantity of samples preclude the use of the traditional methods. A recent development in instrumentation is the diode array spectrometer as exemplified by the Pertem Model DA-7000. This type of instrument is quick to load as it requires no sample cell, and spectral data are acquired very rapidly; typically, an analytical result can be obtained in 15 s.

NIR is used in Australia to predict optimum fertilizer requirements of cereal crops by analysis of total nitrogen and carbohydrate in plant tissue samples. The tissue test for rapid determination of shoot nitrogen status in cereal crops was first developed for rice. The test has since been extended to encompass wheat shoot nitrogen and fructans. The tissue testing system is based on a plant sample taken by the farmer at a specific growth stage (Zadok scale) which is dried and analyzed by NIR. The nitrogen and fructan results are then entered into a database which is used to determine the appropriate fertilizer recommendation.\(^{14}\)

The use of NIR technology to help farm managers understand the fertility of their crops and to segregate or blend grain on its protein content prior to delivery is gaining in popularity. In many countries, the price of wheat is determined by its protein content, often with substantial price increments between grades. This has encouraged some farmers to blend wheat on farm according to its NIR protein to increase their deliverable tonnage of higher priced grain. Providing the farm’s instrument has been properly calibrated and is well maintained, this strategy should be financially successful. Some farmers are also realizing that NIR has the potential to analyze a large number of samples in a short period of time which could enable them to assess their crop for optimum development or to map differences in fertility across fields.

NIR has been used in Australia, Canada, Europe and the USA to monitor growers’ deliveries of wheat and barley for two decades, and some of the first research papers, e.g. Williams,\(^{15}\) described the calibration of instruments for this purpose. Canada was the first grain-producing country to utilize NIR for all wheat protein testing in its segregation program. As well as increased efficiency of the Canadian wheat segregation program, the adoption of NIR testing has resulted in total cost savings to date of CAN$2.5 m. Furthermore, the replacement of the Kjeldahl system, which involves concentrated sulphuric acid and heavy metal catalyst, by the chemical-free NIR method has enabled Canada to lead the way in environmentally safe large-scale protein testing of grain. The Canadian Grain Commission now uses NIR exclusively for providing quality data in support of the marketing of about 50 million tonnes of grain annually.

By 1980, NIR protein testing had become the official method of the US Federal Grain Inspection Service (FGIS) and since then has been in continuous routine use in wheat segregation in the USA. In the USA, following the Grain Quality Improvement Act 1986, hardness measurements have been introduced as part of the wheat grading system. Wheat hardness has been measured in both meal and whole grain. Since there is no international standard reference method for wheat hardness, a definition based on NIR spectra of ground grain has been proposed by Norris et al.\(^{16}\)

Delwiche et al. in the USA\(^{17}\) have carried out a systematic study to develop a wheat classification system for US market class based on NIR protein and hardness measurements on single kernels. This concept is being developed by the FGIS into a practical system for the objective, rapid and sensitive detection of mixtures of wheat classes.

In Europe in the early 1980s, flour millers encountered a need to stimulate the cultivation of higher tonnages of high protein wheat by payment of premiums for protein content. A rapid method of load-by-load testing which produced results acceptable to both farmers and millers became necessary in order to calculate the price on delivery to the mill. NIR was adopted for this purpose in

a number of European countries including UK, Ireland, Germany and Sweden.

Initially, instruments based on reflectance measurements on ground grain were used for testing grain at harvest and these were shown to result in calibrations for protein which were stable over growing locations and seasons and transferable between instruments.\(^{(18)}\) By the mid 1980s, NIT instruments had become available. These instruments typically employ a hopper, into which a sample of whole grain is placed, to dispense the sample into the measurement compartment where it is analyzed by transmittance spectroscopy (Figure 4). Usually, 4–20 subsamples are analyzed sequentially and the results averaged to obtain a more representative result for the sample. The ability to perform protein testing on whole grain eliminates the need for grinding, thus simplifying and speeding up the analysis. Protein calibrations for whole wheat and barley have been shown to perform with equal accuracy to those derived for the ground grain.\(^{(19)}\) However, the criteria for accuracy at reception are more stringent than those for selection of breeding lines. This is because grower payments are determined according to the NIT protein content. In some countries, the payment scale is not continuous but there are cutoffs between different grades where there may be substantial price differentials. Consequently, although the accuracy of NIT calibrations are normally assessed over a wide range, in this case the scatter around a much smaller range becomes important.

In grain trading it is highly desirable to eliminate between-instrument variation in analysis results so that the farmer receives the correct grading and thus fair payment irrespective of the receival silo delivered to. This can be achieved by networking so that small differences in the response of individual instruments are corrected for in the calibration. All instruments in the network are connected to a central computer by modems, allowing simultaneous and uniform calibration and update of all instruments in the network. In 1995, all the European networks were brought together into “The European Grain Network” with the aim of standardizing NIT grain testing throughout the continent.

Paddy rice must be harvested at the optimum maturity to obtain high yield and quality. This is assessed by the moisture content of rice at receival. NIT reflectance instruments are unsuitable for use in rice receival testing because of the high moisture content at which rice is harvested. Following the successful development of NIT calibration for whole rice grain, Australian rice growers have adopted this technology for moisture testing on paddy rice.

The use of NIT technology to determine the protein and moisture contents of both wheat and flour is now routine practice in flour mills worldwide. It is used for testing each delivery of wheat in order to make decisions about acceptance, price and binning; for determination of conditioning time from measurement of hardness; and for analyzing flour to check that it complies with specifications before shipment to the customer. However, the power of NIT goes far beyond mere replacement of wet chemical analysis for raw material and product testing. With the introduction of an NIR instrument into the mill, the laboratory was able for the first time to make a direct contribution to controlling the process in real time. So useful has NIR proved to be for this purpose that in many mills it soon became moved from the laboratory into the mill itself where it could be used off-line by shift millers for process monitoring whenever the mill is running. The success of NIR for this purpose gave it the necessary credibility as a potential on-line sensor in flour mills (see section 3.3).

Many large plant bakeries employ NIR to monitor the quality of their flour and other raw ingredients. Typically, flour would be tested for protein and moisture (possibly, but less commonly, color and water absorption). In biscuit and confectionery bakeries, other ingredients such as sucrose, chocolate etc. may also be analyzed. Having verified the composition of ingredients against their quality specifications, the next point of control of a bakery process is at the dough mixing stage. Detection of faults in the dough avoids energy wastage in baking an out-of-specification product and, for biscuit doughs, may allow the dough to be re-cycled. NIR has been used for compositional analysis of intact biscuit and bread dough pieces and for monitoring the progress of bread dough mixing.

NIR calibrations for compositional analysis of short-sweet biscuit doughs enabled the simultaneous detection of errors in fat of 5% relative to the total amount of fat in the recipe and gross errors in the water, sucrose and flour percentages.\(^{(20)}\) NIR has also been used to determine the protein and fat contents in bread dough.

During baking, the moisture content of doughs is reduced from about 18% to 2% for biscuits and 60% to 40% for bread. Monitoring the changes in the moisture content during baking allows the oven performance to be optimized. However, this is not easy because there is a non-uniform distribution of water content through both the dough and the freshly-baked product.

For biscuits, an Infrared Engineering MM55 Gauge (see section 3.3) is commonly used to monitor the moisture contents of biscuits on a conveyor as they leave the oven. This measurement depends on a reproduceable relationship between the gauge reading which represents the surface moisture content in the freshly-baked biscuit and the bulk moisture content of the fully equilibrated product in packet and on strategies to compensate for the discontinuous nature of discrete products on a conveyor.

NIR is applicable to the analysis of moisture, protein, fat, starch, sugars and fiber in intact cereal foods such as bread, biscuits, cake mixes, breakfast cereals, pasta and snack foods (Table 2).

NIR has been applied to the measurement of the rate of staling of white bread crumb without the use of a reference method.21 Rate constants were calculated directly from plots of second derivative NIR data versus time. This is a rare example in food research where NIR has been used as a primary method.

5.2 Milk and Dairy Products

Milk analyzers based on mid IR spectroscopy have been available since the 1960s but it was not until much later that NIR began to be used in the dairy industry. Although the mid IR is satisfactory for the proximate analysis of liquid milk, dairy chemists are faced with one of the widest ranges of sample types in the food industry. NIR has a key role in the analysis and process control of dairy products. It offers flexibility in the analysis of protein, moisture, fat and lactose contents in a wide range of dairy products including:

- liquid milk
- dried whole milk, skim milk and whey powders
- cream
- traditional and processed cheese.

Many of these products are emulsions whose sampling for classical chemical analysis is difficult. For example, blending such samples changes their physical characteristics. NIR offers the possibility of on-line analysis which avoids the need for batch sampling and minimizes sampling error by averaging of virtually instantaneous, continuous measurements. Milk powders are analyzed on-line using a powder analyzer which enables the moisture content to be controlled. For most other on-line applications, fiber-optic probes are used. These have the advantages of minimal maintenance owing to the absence of moving parts, robustness to high temperatures and pressures and the survival of clean-in-place protocols involving the use of caustic chemicals. Two examples of on-line NIR fiber-optic measurement in dairy processing are moisture control of cream cheese and processed cheese. Cream cheese is manufactured in a series of set tanks from which product is transferred into a separator. NIR monitoring of the product from the separator enables compensation for the variation in characteristics from different set tanks. NIR measurements of processed cheese have been used for process diagnostics in which a greater understanding of the effect of temperature on the final moisture content has been gained.

The extent of development of NIR applications in the dairy industry is such that it is possible to purchase an instrument which is factory-calibrated for proximate analysis of cheddar cheese. However, these calibrations are only valid for cheddar made to the traditional recipe and sampled directly from the vat; non-traditional and matured cheddars require different calibrations.

5.3 Meat

NIR spectroscopy is widely used in the meat industry for proximate analysis. A special interactance fiber-optic probe has been designed to spear carcasses and determine their fat content. This enables the carcasses to be sorted prior to butchering.

Dedicated instruments are available to determine the protein, fat and moisture contents of ground meat and meat products and factory-set calibrations are available for cooked meat, cooked ham, liver sausage, and pepperoni. Meat samples are minced then blended in a food processor before being packed into an open sample cell. The amount of sample needs to be controlled either by mass or by depth.

Isaksson et al.22 have used the MM55 on-line gauge (see section 3.3) for proximate analysis of ground beef directly at a meat grinder outlet. NIR has also been used for sensory analysis of sausages and to discriminate between fresh and frozen-then-thawed beef.

5.4 Fish

The analysis of farmed atlantic salmon and rainbow trout enables the optimization of their processing. NIR fiber-optic interactance probes can be used to measure nondestructively the protein, moisture and oil contents of whole fish.23

5.5 Fruit and Vegetables

Fresh fruit and vegetables are graded by shape, size and color. Objective, nondestructive methods of sorting enable growers and packers to market a consistent product over an extended season. In addition, high-quality produce can be segregated for high-return markets while
lower-quality produce can be identified for processing or other uses.

The nondestructive sorting of fruit for ripeness by optical spectroscopy was originally carried out in the visible region. However, the availability of fiber-optic interactance probes led to a resurgence of research interest in this application via the determination of sugar content. The reason for developing a direct measure of sugar content of fruit is that appearance is not a reliable guide to sweetness. Japanese researchers have demonstrated the successful application of NIR to the on-line determination of sugar content in intact peaches and mandarins and developed an automated fruit sorting machine based on this principle. Australian scientists have extended this concept to tropical fruits such as melons, mangoes and pineapples.

5.6 Confectionery

NIR applications in the confectionery industry include the determination of moisture in granulated sugar and chocolate crumb, protein and oil in cocoa powder and fat in whole chocolate. NIR data have also been shown to correlate highly with sensory data on raw and roasted cocoa beans, chocolate mass and finished chocolate.

5.7 Beverages

When barley is germinated under controlled conditions, it undergoes a series of complex biochemical reactions which result in its conversion to malt. The malt is then mashed with water to produce a liquid called wort which is then fermented to produce beer. Since malting takes about twelve days, barley breeders need a rapid means of predicting the malting quality of barley grain. Calibrations have been developed for nitrogen, lysine, β-glucan and malt hot water extract. As with wheat functional quality, NIR analysis of barley is used to predict the quality of material which is derived by processing of the grain and there is doubt whether tests on ungerminated grain fully account for the interaction of enzymes and substrates during germination. Attempts have been made to improve the accuracy of prediction by analysis of key quality characteristics of the malt or the wort (Table 3).

In the brewing industry, NIR is widely used to monitor the original gravity and alcohol content of beer using online flow-through cells. Standard errors of the calibration for alcohol of 0.1–0.2% have been reported using either transmittance or transfectance cells. The Liquidata probe has been used to achieve a process guarantee on any beer to better than ±0.04% alcohol.

NIR is used to monitor fruit quality and determine the alcohol content of wine and dedicated filter instruments for wine analysis are commercially available.

Other beverage applications include the moisture content of tea and coffee, sugar content of fruit juices and the sensory quality of tea and coffee blends.

5.8 Authenticity

The study of food authenticity involves establishing whether a sample is genuine in terms of its description, including geographical origin. Many analytical techniques have been used to examine the authenticity of a wide range of different foods. The applications of NIR for authenticity testing of coffee, fruit pulps, milk powders, orange juice, pig carcasses, rice, sausages, sugars, vegetable oils, wheat grain and wheatflour have been reviewed by Downey. These applications are based on the principles of discriminant analysis (see section 4.4) in which the problem is to compare the spectrum of the test sample with a reference library (see section 4.2). The library should contain examples of known authentic and adulterated samples. In the simplest case, the question is simply whether the test sample belongs to one of two populations such as “Basmati rice” or “not Basmati rice”. Often, however, it is required to classify within a series of possible classes (e.g. different vegetable oils or wheat varieties), to identify a particular kind of adulteration (e.g. medium invert beet sugar, pulp wash or zest oil in orange juice) or to quantify an adulteration (e.g. non-dairy fat in milk products).

6 THE LITERATURE

Scientific papers describing the practical applications of NIR in food analysis are spread widely throughout the literature. As evidenced by the key references cited in this article, such papers may be found in journals devoted to analysis, spectroscopy, general food science or more specialized areas of food science. This makes it particularly difficult to search the literature. However, NIR News (NIR Publications, Chichester, UK) has since
1990 included a references section in an attempt to overcome this problem.

The only scientific journal devoted exclusively to NIR spectroscopy is *Journal of Near Infrared Spectroscopy* (NIR Publications, Chichester, UK). Volume 4 was dedicated to Karl H Norris, the founder of modern NIR analysis. It contains historical, review or leading edge papers by many of the pioneers of NIR spectroscopy and provides a particularly valuable introduction to the technique.

The proceedings of the series of international conferences on near-infrared spectroscopy (ICNIRS) provide a valuable addition to the literature on the developments in and applications of NIR spectroscopy:

There are only two books currently in print devoted to NIR analysis:

### 7 STANDARD METHODS

The following standard methods of NIR analysis of foods have been adopted:

**American Association of Cereal Chemists (AACC)**

**Association of Official Analytical Chemists (AOAC)**

**International Association for Cereal Science & Technology (ICC)**

**Royal Australian Chemical Institute (RACI) Cereal Chemistry Division**
- Method No. 11.01 Determination of protein and moisture in whole wheat and barley by NIR. First Approved: 1998.

### ACKNOWLEDGMENTS

The author thanks Mrs S. Ormston for preparation of the original artwork used in this article.

**REFERENCES**

This article presents an overview of nuclear magnetic resonance (NMR) methods and their applications in probing the metabolic processes in plants and interaction between plants and soils. The basic principles of both solution- and solid-state NMR are introduced, with an emphasis on useful parameters that can be employed for determining covalent structures and conformations of biomolecules and their environmental derivatives. Both one-dimensional (1-D) and two-dimensional (2-D) NMR techniques are described, and the advantages of improved resolution and information content for the 2-D techniques are demonstrated. The substantial improvement in the sensitivity of inverse detection methods for detecting heteronuclei is also shown. Instrumental considerations as well as sample preparation requirements are described for in vivo and in vitro applications and analysis of small and macromolecules. Applications of multinuclear 1-D and 2-D NMR in plant metabolism and plant–soil interactions are illustrated. These include in vivo measurements of subcellular compartmentation, determination of metabolite concentrations, enzyme or exchange kinetics, in vitro analysis of plant tissue extracts and root exudates, use of stable isotope tracers for analysis of biochemical pathways, and structural and conformational characterization of natural organic matter (NOM) from soils and sediments. The relative advantages and disadvantages of solution- and solid-state NMR techniques for analysis of plant–soil systems are discussed with examples from characterization of NOM, although 1-D $^{13}$C solid-state methods have been of choice due to the polydispersive nature and low aqueous solubility of NOM. However, recent advances in 2-D solution-state methods are presented that provide valuable information on structure, conformation, and ligand binding of NOM, which is not practical by solid-state methods. The limitations of NMR analysis for in vivo, in vitro and NOM are noted, along with a discussion on future prospects for NMR analysis in terms of spectral resolution and detection limits achievable.
absorption (resonance) frequency is low. For magnetic field strengths commonly available, the proton resonates in the range 100 to 600 MHz. Other nuclei resonate at lower frequencies, e.g. $^{31}$P at 40%, $^{15}$N at 10% and $^{13}$C at 25% of the proton frequency.

### 1.2 One-dimensional Nuclear Magnetic Resonance

All 1-D spectra consist of a number of peaks or bands that can be characterized by a small number of parameters. These are the chemical shift, spin–spin coupling, peak area, and peak width at half height. Each parameter has a physical significance that can be related to chemical bonding, relative amounts of material, and dynamic properties, respectively.

#### 1.2.1 Chemical Shift

In NMR, the resonant frequency of a peak is usually referenced to a standard, and expressed as a ratio to the external field strength in parts per million (ppm). This ratio is defined as the chemical shift, which is sensitive to the local chemical bonding. Therefore, it is possible to identify protons in different chemical groups on the basis of their chemical shifts. Compound identification can be obtained by matching the chemical shifts of the unknown compound to those of the standard. For example, alanine can be assigned by two $^1$H resonances at 1.47 ppm (methyl) and 3.77 ppm (CH), respectively (Figure 1a). Note also that the peak areas are in the ratio 3:1 reflecting the relative amounts of the methyl and methine protons. A large data base for $^1$H chemical shifts of biological compounds is available.\(^{(7,8)}\)

Chemical groups can also be identified using nuclei other than $^1$H. In phosphorylated compounds, the $^{31}$P-NMR chemical shifts of phosphate monoesters and diesters are quite distinct, as are the shifts of polyphosphates such as in adenosine 5'-triphosphate (ATP). Similarly $^{15}$N chemical shifts are characteristic for amino, amido, and imino groups. $^{13}$C-NMR is particularly useful for identifying carbonyls, quaternary carbons, and many protonated aliphatic and aromatic carbons because of its large dispersion of chemical shifts (>200 ppm) and the extensive data base for biological compounds.

#### 1.2.2 Spin–Spin Coupling (Scalar Interactions)

The magnetic nuclei can interact with other nuclei in the same molecule by two distinct mechanisms, each providing different information about the chemical structure. The first is the ‘scalar interaction’, in which a nucleus senses the spin state of another nucleus through the bonding electrons. This spin–spin coupling is most effective over a limited number of bonds (typically up to four covalent bonds), and is manifested by splitting of the peaks as shown in the alanine spectrum in Figure 1(a). The methyl protons are split into two lines, whereas the methine proton is split into four lines having intensities in the ratio 1:3:3:1. In general, a proton that interacts with $n$ other protons is split into $n + 1$ lines, with intensity ratios given by the binomial coefficients. The magnitude of the splitting is the coupling constant, denoted $J$. Typical ranges of coupling constants include $J_{\text{CH}} \approx 120–200$ Hz, $J_{\text{CC}} \approx 40$ Hz, $J_{\text{NH}} \approx 70–90$ Hz, $J_{\text{CH}} \approx 1–10$ Hz. $J$ depends on a number of factors including the chemical nature of the coupled spins, the number of bonds, the bond multiplicity, and torsion angles. For example, the three-bond coupling constant in such a structure as H$\alpha$CCH$\beta$ depends on the torsion angle about the central C=C bond. Since the coupling constant varies from a lower limit (H$\alpha$H$\beta$ gauche) to an upper limit (H$\alpha$H$\beta$ trans), its value provides a way of determining the dihedral (or torsion) angle. The relationship between the magnitude of the coupling constant and the dihedral angle is given by the Karplus equation (Equation 1):

$$
J = A + B \cos(\phi) + C \cos^2(\phi)
$$

where $\phi$ is the dihedral angle.

The three constants $A$, $B$ and $C$ have been determined for a wide range of compounds (allowing for variations from electronegativity of substituents on the carbon atoms).

#### 1.2.3 Relaxation

In addition to the through bond interaction, nuclei can also interact through space. Once the nuclei are excited by absorbing radiation, they can be returned to the ground state by an exchange of magnetization between the sample nuclei and their surroundings. This general process is termed relaxation. There are several mechanisms by which the nuclei can relax, but the most important one is dipole–dipole coupling between spins that are close in space. The strength of this interaction depends on the size of the nuclear magnetic moments, the angle between the field direction and the vector between the two nuclei, how fast the molecule is rotating, and the inverse sixth power of their distance ($r$) from each other. The magnetic moments are known properties of a given nucleus, while in solution, the random motion of the molecules causes the angular part to average to zero. This leaves only two unknown parameters: the distance between the spins and the rate of the motion. If one of the two is known, the other can be determined through measurement of dipole–dipole coupling.

The process by which the nuclei give up their excess magnetic energy to the surroundings is called spin–lattice relaxation, and is characterized by a time constant $T_1$. $T_1$ determines how long a system takes to re-establish

Figure 1 1H-NMR spectra of L-alanine (a) and L-glutamate (b) in D2O. All spectra were recorded at 25°C at 14.1 Tesla. In the 1-D spectrum of alanine (a), the peaks at 1.47 ppm and 3.77 ppm are the βCH3 and αCH resonances, respectively, while the labels above denote the relative intensities (1:3:3:1 and 1:1) and areas of their multiplet components, respectively. The multiplets result from scalar coupling between the αCH and βCH3 resonances. In plot (b), the 2-D correlation spectroscopy (COSY) (upper triangle) and total correlation spectroscopy (TOCSY) (lower triangle) spectra of glutamate are combined and presented as contour plots. Lines connecting the cross-peaks to the diagonal peaks indicate the presence of scalar coupling. Note that the cross-peak between the αCH and γCH2 resonances in the TOCSY spectrum is missing in the COSY spectrum. This is because only 2–3-bond couplings are detected in COSY spectra while couplings beyond three bonds are also observed in TOCSY spectra.

The equilibrium condition: typically $T_1$ values lie in the range of a few milliseconds to a few seconds. The spin–lattice relaxation involves only the component of the magnetization parallel to the polarizing magnetic field (conventionally z). For this reason it is also called longitudinal relaxation. There is a second relaxation process which occurs in the plane perpendicular to the magnetic field (transverse relaxation). Interactions between spins while rotating in the x–y plane cause loss of phase coherence, which involves a change in the entropy instead of the energy of the system. The time constant for this process is $T_2$ (spin–spin relaxation time). $T_2$ also determines the breadth of each NMR line with the width at half height (or line width) equal to $1/pT_2$.

These relaxation processes are important because they affect the sensitivity of the experiment and the types of NMR experiments that can be performed. The $T_1$ value is also important where quantitation is desired for the following reasons. The NMR signal is directly proportional to the number of spins in the detection region (i.e. the concentration of a given sample). However, if insufficient time is given between excitation pulses to allow the system to return to equilibrium, then a reduced signal will be obtained depending on the value of $T_1$. Different nuclei can have different $T_1$ values so that under conditions of rapid pulsing, the observed signal would not be proportional to the concentration of the spins. This is particularly problematic in 13C-NMR where the 13C nucleus is relaxed by the directly attached proton. As the relaxation rate is proportional to the number of attached protons, the values of $T_1$ are quite different for CH3, CH2, CH and quaternary carbons. Fortunately, $T_1$ can be directly measured, and the observed intensities corrected in a straightforward manner.\(^2\)

Since dipole-induced $T_1$ and $T_2$ processes involve all nuclei that are close in space, it is possible to measure the interaction between pairs of nuclei by cross-relaxation. The dipolar interaction that involves mutual
exchange of magnetization leads to a change in peak intensity, and is limited to spins that are ≤5 Å apart. This phenomenon is known as the nuclear Overhauser effect (NOE). The NOE is a measure of the strength of the dipole–dipole interaction between a pair of spins. As this interaction depends on \( r^{-6} \), it provides a means of measuring short distances between pairs of nuclei within a molecule. The combined measures of dihedral angles and interproton distances form the basis of three-dimensional (3-D) structure determination for biomacromolecules. Magnetization can also be transferred by a physical exchange of spins between two sites or molecules, such as in ligand binding (free and bound states) and conformational exchange. These magnetization exchange experiments can be used to measure the kinetics of processes that occur on the timescale of \( T_1 \). Examples of this application are the analysis of unidirectional fluxes for ATP synthesis and hydrolysis. 

1.2.4 Sensitivity Enhancement

The intrinsic sensitivity of a nucleus is determined by its gyromagnetic ratio (\( \gamma \)), which in turn determines the magnitude of the nuclear magnetic moment and its resonance frequency. Since the proton nucleus \((1\text{H})\) has far greater sensitivity than heteronuclei such as \(^{13}\text{C}\) and \(^{15}\text{N}\), the sensitivity of protonated X nuclei can be increased by transferring proton magnetization to the attached X nucleus via the scalar coupling using insensitive nuclear enhancement by polarization transfer (INEPT). This increases the sensitivity by a factor \( \gamma_{\text{H}}/\gamma_{\text{X}} \) which amounts to 4- and 10-fold for \(^{13}\text{C}\) and \(^{15}\text{N}\), respectively.

The X-nucleus peak will also be split by scalar coupling from directly attached protons (\( ^2 J \)) or by long-range (\( ^2 J \) and \( ^2 J \)) coupling to protons, leading to both reduced sensitivity and resolution. It is therefore common to decouple the protons by broad-band irradiation. This averages the effects of the proton and causes the X resonance to collapse into a singlet, with a concomitant increase (>twofold) in sensitivity and resolution. Irradiation of the protons is also accompanied by NOE for the X nucleus. For \(^{13}\text{C}\), the NOE is always positive, and can enhance the signal up to threefold for small molecules, but for larger molecules, the NOE may be <20%. Since the gyromagnetic ratio of \(^{15}\text{N}\) is negative (i.e. it rotates counter clockwise compared with \(^1\text{H}\) or \(^{13}\text{C}\)), the NOE can lead to a fourfold negative enhancement of the signal for small molecules, and a slight reduction in signal strength for large molecules. For intermediate sized molecules, the signal can disappear completely. Therefore, signal enhancement via NOE for \(^{15}\text{N}\) needs to be considered carefully.

Since both \(^{13}\text{C}\) and \(^{15}\text{N}\) are present at low natural abundance (1.1% and 0.37%, respectively), the sensitivity of the experiments can be further improved by isotopic enrichment. The \(^{13}\text{C}\) and \(^{15}\text{N}\) labels in the enriched molecules can be selectively detected in complex mixtures, using the heteronuclear indirect detection methods described below. Indirect detection of the X nucleus via their attached protons can improve the X nucleus sensitivity to approach that of the proton nucleus. The conventional sensitivity barrier of heteronuclear experiments is thus greatly diminished and their applications to agricultural problems will be much more fruitful.

1.3 Two-dimensional Nuclear Magnetic Resonance

1.3.1 Direct Detection

Although 1-D NMR can contain sufficient information to determine structures and conformational properties of simple molecules, this is not the case for large molecules or mixtures of molecules due to the limitation in spectral resolution and obtainable structure parameters. These problems can be alleviated by two complementary approaches, which can be combined to further improve resolution. The first approach is to increase the magnetic field strength for better signal separation as the latter is directly proportional to the former. The second approach is to increase the number of frequency dimensions. Thus, in 2-D NMR, signals are spread out over a plane composed of two frequencies, instead of along a line as in 1-D NMR. To achieve this, there must be an interaction between pairs of spins. There are two mechanisms by which magnetization can be exchanged between spins, namely the scalar (\( J \)-coupled) interaction and the dipolar interaction.

In the basic COSY type of experiments, protons that interact via scalar coupling with other protons are observed as resonating at two frequencies. The spectral representation is usually in the form of a contour plot, where the off-diagonal elements or cross-peaks (symmetric with respect to the diagonal) indicate such scalar interactions (Figure 1b). As scalar coupling is observed between protons separated by up to four covalent bonds, the cross-peaks in a COSY spectrum provide a “map” of the covalent connectivity of a molecule. Additional information of this kind can be obtained by TOCSY, also known as HOHAHA (homonuclear Hartmann–Hahn). In this experiment, all spins that form a scalar-coupled system give rise to cross-peaks. Giving glutamate as an example (see Figure 1b for structure), only two sets of cross-peaks are observed in the COSY experiment, i.e. between the two protons of the first two carbons, and between those of the second and third carbons (e.g. Figure 1b). In contrast, in the TOCSY experiment, cross-peaks are also observed between the protons attached to the first
and third carbons (Figure 1b). This can be valuable in crowded spectra where some cross-peaks are obscured by spectral overlap and in tracing covalent bond networks of a given molecule.

Another major 2-D method of correlating spins is by making use of the dipole–dipole interaction or NOE, which is known as nuclear Overhauser effect spectroscopy (NOESY). The NOE is transmitted through space, and its magnitude provides an estimate of the distance between spins, independent of the number of bonds between them. It is therefore extremely valuable for determining the conformation of folded molecules (secondary and tertiary structures) such as polypeptides, polysaccharides and nucleic acids\(^{1,6}\) or interaction of small molecules with macromolecules such as humics.\(^{12}\) It also provides a means for observing interactions between subunits in a polymer (quaternary structure), where no scalar coupling interaction can be detected. Moreover, it is very useful for determining the conformations of small, rigid molecules, especially in conjunction with the quantitative analysis of scalar coupling constants. The NOE across the glycosidic linkage can be used for determining the sequence and conformation of oligosaccharides.\(^{13}\) In small molecules (\(M < \text{ca. } 1 \text{kDa}\)) the \(^1\text{H}–\text{H}\) NOE is positive, corresponding to an increase in signal. For macromolecules (\(M \gg 1 \text{kDa}\)), the NOE is negative (decrease in signal). This implies that at some molecular size (or rotational correlation time), the NOE can become zero, irrespective of the proton–proton distance. However, there is an NOE analog of the TOCSY experiment called ROESY (rotating frame Overhauser effect spectroscopy) for which the effect is positive for all molecular sizes.\(^{13,14}\) This experiment is preferred for oligopeptides and oligosaccharides of \(M \approx 1000 \text{Da}\) or for flexible molecules where the correlation time is short.

The cross-peak patterns and chemical shifts observed in COSY and TOCSY experiments can help define the structures of molecular fragments and even of entire molecules in complex mixtures such as crude extracts of plant tissues without sample fractionation.\(^{7,8,15}\) A significant limitation is in identifying functional groups containing heteroatoms, and in connecting molecular fragments separated by NMR-inactive heteroatoms such as oxygen. This can be overcome by using heteronuclear 1-D and 2-D NMR techniques. For example, amino and amido groups can be distinguished in 1-D \(^{15}\text{N}\)-NMR, as can carbonyl, aromatic, and aliphatic quaternary carbons in \(^{13}\text{C}\)-NMR, and phosphate monoesters and diesters in \(^{31}\text{P}\)-NMR. It is also feasible to correlate the heteronucleus with protons in 2-D heteronuclear correlation (HETCOR) experiments.\(^{16}\) However, these direct detection heteronuclear methods suffer from low intrinsic sensitivity, which means a requirement for larger amounts of sample.

### 1.3.2 Indirect Detection

In addition to having a low intrinsic sensitivity, heteronuclei such as \(^{13}\text{C}\) and \(^{15}\text{N}\) are present at low natural abundance (1.1% for \(^{13}\text{C}\) and 0.37% for \(^{15}\text{N}\)), which further decreases the overall sensitivity. Hence, it is highly desirable to obtain \(^{13}\text{C}\) and \(^{15}\text{N}\) spectra with the sensitivity of the proton. This can be achieved by the “indirect detection” methods. In the simplest 2-D HSQC (heteronuclear single quantum coherence) experiment,\(^{17}\) the magnetization of the proton is transferred to the hetero (X) nucleus by INEPT, and the X nucleus is then allowed to precess for different amounts of time to label with X frequency. The magnetization is then transferred back to the attached proton for detection, which increases the sensitivity by \(\left(\frac{\gamma_\text{H}}{\gamma_X}\right)^3\). This represents a signal enhancement of 64-fold for \(^{13}\text{C}\) and 1000-fold for \(^{15}\text{N}\).\(^{18}\) HSQC is mainly useful for detecting X nuclei with directly bonded proton(s), which means that carbonyl, tertiary nitrogens, and quaternary carbons and nitrogens are not detected. However, it is possible to correlate protons and an X nucleus over two or more bonds. For example, a long-range HSQC experiment can be performed for \(^{31}\text{P}\) or \(^{15}\text{N}\) since, for most compounds, the X nucleus is isolated (i.e. no N–N or P–P coupling) so that there is only one or two possible coupling pathways to the protons. Other methods of correlating protons to a heteronucleus have also been reported, which in effect produces an X-edited TOCSY (HeteroTOCSY).\(^{19,20}\) For carbon long-range coupling, the HMBC (heteronuclear multiple bond correlation) experiment\(^{21}\) may be applied, which correlates carbons with protons 2–4 bonds away, and is therefore valuable for detecting carbonyl and quaternary carbons.

The X-edited 2-D experiments provide a powerful means for identifying isotopically enriched compounds and the position(s) of their isotopic labels. When spectral resolution permits, the degree of enrichment in proton experiments can be determined from the labeled satellites and the non-labeled central peak. The ratio of the satellite peak area to the total peak area is equal to the fraction of the enrichment. These capabilities will be invaluable in tracer studies where the fate and transformation of both natural products and anthropogenic pollutants in the plant–soil environment are probed.

### 1.4 Instrumental and Sample Considerations

For small molecules (\(M \leq 500\)), all of the aforementioned experiments can be successfully performed with relatively low concentrations of solutes (in the sub millimole range) on a modern spectrometer operating at 11.75 to 14.1 T (500 and 600 MHz for \(^{1}\text{H}\), respectively). With \(^{1}\text{H}\) detection, a 1-D NMR spectrum can be obtained within a few minutes at 10 µM in a volume of 0.5–0.6 mL (0.3 mL with special Shigemi tubes), i.e. at \(\lesssim 5\) nmol.
Mixtures of metabolites can be resolved and identified by TOCSY in an overnight run at ca. 100 μM concentration, which is typically obtainable from <10 mg of dry plant tissues. The HSQC can be performed in a few hours at natural abundance at similar solute concentrations for 13C, and with isotopic enrichment a reasonable spectrum can be recorded at much lower concentrations in a similar time.

For large molecules such as proteins, nucleic aids, and humic substances, the sensitivity is generally poorer because the resonances become broader due to a faster spin–spin relaxation (i.e. short T2 values) similar to that in the solid state, the solid-state resonance is a broad envelope that reflects the many orientations of each nucleus with respect to the magnetic field. Hence, an alternative means of averaging the dipolar interactions and chemical shifts must be used to improve the spectral resolution. Spinning the sample at high speed at the “magic angle” (cos⁻¹(1/3)⁻0.5 = 54.74°) causes the dipolar and chemical shift anisotropy interactions to average. The rotation speed has to be higher than the characteristic frequency range of the observed nucleus, which for 13C is a few kHz. Magic angle spinning (MAS) is performed routinely in solid-state 13C-NMR.

For the low natural abundance nuclei such as 13C, the solid-state measurements suffer the same sensitivity problem as the liquid-state analysis. To improve sensitivity, the larger proton magnetization is transferred to the X nuclei through dipolar coupling. This is in practice achieved by Hartmann–Hahn matching, in which strong radiofrequency fields are applied simultaneously to the protons and X nucleus, with intensities proportional to their gyromagnetic ratios. Such magnetization transfer from the abundant protons to the dilute X nuclei is known as cross-polarization (CP) transfer. The efficiency of the transfer is a function of the chemical composition and relaxation properties. In addition, the large reservoir of fast relaxing protons allows more rapid acquisition of the X signal, which means that a higher signal intensity can be recorded in a shorter duration. The combination of CP transfer and MAS (CP/MAS) with 13C-NMR has been widely applied to soils, where chemical shifts have been used to reveal the chemical groups of the organic matter present. However, reliance on the chemical shift information alone can lead to ambiguities in assignments (see below for a more detailed discussion of assignment strategies).

2 APPLICATIONS IN THE PLANT SOIL ENVIRONMENT

2.1 Plant Metabolism

2.1.1 In Vivo Nuclear Magnetic Resonance

Ideally, one would like to measure metabolic processes in situ so that spatially and temporally resolved physiological/biochemical reactions can be determined. This capability is vital to the understanding of all life processes since maintenance of distinct cellular and organ compartments is required for the proper functioning of the metabolic machinery. In vivo NMR represents one of the few analytical tools that possess this capability.
2.1.1.1 Sample Preparation  The types of agriculture-related samples that have been studied in vivo by NMR include whole seedlings, excised plant tissues (root tips, mature roots, shoot tips, leaf blades), as well as plant, fungal, and algal cell cultures. Among these, root tips are the most commonly investigated, due to their high metabolic activity and strong NMR signals obtainable. To implement in vivo NMR studies of plant/fungal/algal metabolism, the sample needs to be maintained under physiologically relevant conditions. This entails supply of oxygen and nutrients, removal of waste products, and illumination in the case of photosynthetic tissues. The former two requirements can be met with superfusion systems for whole plants and excised plant tissues or airlift systems for plant cell suspensions. However, implementing uniform and optimal illumination has been problematic for investigating photosynthetic processes in leaf tissues. For algal suspensions, utilizing fiber-optic cables for light delivery appeared promising but further development is needed for working with suspensions of high cell densities. The latter is important for obtaining NMR spectra of good signal-to-noise ratios. It should also be emphasized that care must be taken to avoid complications from tissue wounding and aging processes in performing in vivo NMR experiments with excised plant tissues. That is, experiments should be conducted after initial stabilization of the excised tissues and before significant tissue deterioration occurs.

2.1.1.2 Information Obtainable  In vivo NMR has been utilized to measure both steady-state and dynamic processes in plants, fungi, and algae. The following types of information are available:

- tissue content and changes of NMR-observable inorganic and organic metabolites (see references below);
- intracellular pH (see references below);
- subcellular distribution of inorganic and organic metabolites, most commonly in the cytoplasm and vacuole;
- enzyme or exchange kinetics.

In vivo observable tissue metabolites in plants, fungi, and algae include a number of organic acids, amino acids, and carbohydrates by 1H-NMR borate and borate esters by 11B-NMR, storage carbohydrates and triglycerides by natural abundance 13C-NMR, nitrate, ammonium, and some quaternary ammonium compounds by 14N-NMR, sodium ion by 23Na-NMR, aluminum–polyphosphate complexes by 27Al-NMR, inorganic phosphate, various phosphate ester (including high-energy nucleoside triphosphates), and polyphosphates by 31P-NMR, and potassium ion by 39K-NMR. Using stable isotope tracers, 13C- and 15N-labeled metabolites including amino and organic acids, mobile and storage carbohydrates, polysaccharides, and secondary metabolites in plants and associated microbes have been detected in vivo by 13C- and 15N-NMR.

For measuring intracellular pH, 31P-NMR is by far the most frequently used tool because several phosphate metabolites, most notably inorganic phosphate, have pH values within 1–1.5 units of the plant cell pH. For example, the chemical shift of inorganic phosphate (pKa = 6.8) is sensitive to pH in the range of 5.5 to 8 and consequently two distinct signals (corresponding to cytoplasmic and vacuolar inorganic phosphates) are typically observed in 31P-NMR spectra of plant tissues in vivo (see Figure 2). From the chemical shifts and appropriate titration curves of inorganic phosphate, the pH of the plant cell compartments can be determined to within ±0.1 units near pH 7 (poorer at the extreme ends of the titration curve). Relative changes in intracellular pH such as those induced by salinity (Figure 2) can be measured in real-time to within ±0.05 pH units accuracy. Other metabolites including histidine, 13C-bicarbonate, and fluorinated amino acids are also useful as intracellular pH probes, via 1H-, 13C-, and 19F-NMR analysis, respectively. Also shown in Figure 2 are signals arising from other important phosphate metabolites including nucleoside 5’-triphosphates (NTPs), nicotinamide adenine dinucleotide phosphate (NADP) and its reduced form, uridine 5’-diphosphate glucose (UDP-Glc), and sugar phosphates. Phosphodiester signals may be observed in some systems such as sycamore cell suspensions (Figure 3).

The distinction between cytoplasmic and vacuolar inorganic phosphates illustrates the value of in vivo NMR for measuring the subcellular distribution of metabolites. In principle, metabolite compartmentation can be followed by in vivo NMR, provided that the NMR signals of a given metabolite are sufficiently sensitive to the compartment conditions (e.g. pH, ionic strength, paramagnetic ions) such that their location can be differentiated by chemical shifts and other NMR parameters (e.g. relaxation behavior). Figure 4 demonstrates an in vivo 13C-NMR analysis of malate and citrate compartmentation in the cytoplasm and vacuole of sycamore cells. The respective localization of histidine and malate in the vacuole and cytoplasm of maize roots was demonstrated via in vivo 1H-NMR analysis. The intra- and extra-cellular localization of sodium ions in plant tissues was achieved with the use of a shift reagent and 23Na-NMR.

In terms of dynamic processes, analysis of unidirectional rates of ATP turnover by the 31P-NMR saturation transfer technique represents a unique and powerful...
Figure 2 In vivo 31P-NMR spectral changes of Sorghum bicolor root tips as a function of NaCl treatments. The dashed line denotes the change in the peak position of the cytoplasmic inorganic phosphate (Pi) signal from S. bicolor root tips as a result of treatment with increasing concentrations of NaCl (in mM). Peaks are labeled as 1, glucose-6-phosphate; 2, cytoplasmic Pi; 3, vacuolar Pi; 4 and 5, terminal and α-phosphate of nucleoside tri- and diphosphates (γ nucleoside 5’-triphosphate (NTP) + βNDP, αNTP + αNDP), respectively; 6, NADPH + UDPH; 7, UDPG; and 8, β-phosphate of nucleoside triphosphate (βNTP). application for in vivo NMR. This technique measures the exchange process (i.e. magnetization exchange) between ATP and inorganic phosphate as catalyzed by the mitochondrial ATPase. By following the transfer of magnetization from the γ resonance of ATP to the inorganic phosphate resonance or vice versa, the unidirectional rates of ATP synthesis or hydrolysis can be deduced by taking into account the spin–lattice relaxation and other competing reactions (see Figure 5 for an example). Another common application of in vivo NMR is to follow the changes in metabolic processes with time. This can be performed with or without stable isotope tracers. For example, the time courses of changes in energy metabolism and intracellular pH in plant tissues under hypoxic stress were followed in vivo by 31P-NMR, while complementary changes in fermentation metabolism were revealed by 1H-NMR. In vivo NMR analyses that unveil novel metabolic changes under other plant stress conditions (e.g. pH, salinity, sucrose starvation) have also been reported, largely employing 31P-NMR (see reviews by Ratcliffe). The 1H- and 31P-NMR applications were performed without labeled tracers since the natural abundance of these two nuclei is virtually 100%.
NUCLEAR MAGNETIC RESONANCE IN ANALYSIS OF PLANT SOIL ENVIRONMENTS

In vivo $^{31}$P-NMR measurement of malate and citrate compartmentation in sycamore cells treated with 5 mM $\text{H}^{13}\text{CO}_3^-$. The two series of spectra were acquired from perfused sycamore cells in the absence (a) and presence (b) of 0.5 mM Mn$^{2+}$. In (a), cytoplasmic and vacuolar malate signals were observable but severely overlapped, while those for citrate were not discerned. With the addition of Mn$^{2+}$ as in (b), the vacuolar signals for malate and citrate were suppressed, thus allowing their cytoplasmic signals to be observed. The difference spectrum of (a) and (b) (a/b) revealed the vacuolar signals of malate and citrate. (Reprinted from Gout et al., © 1993, with permission of The American Society for Biochemistry & Molecular Biology.)

In contrast, $^{13}$C- or $^{15}$N-enriched tracers are invariably used to measure metabolic changes in vivo via $^{13}$C- or $^{15}$N-NMR, due to the low natural abundance of these two nuclei. Such labeled tracer studies can also provide metabolic flux and pathway information that is difficult to obtain otherwise. Moreover, isotopic enrichment improves detectability such that in vivo 2-D NMR measurements can be performed for a more reliable assignment of resonances observed in vivo. Examples of in vivo $^{13}$C- and $^{15}$N-NMR applications are shown in Figures 6 and 7, respectively. In Figure 6, the synthesis of trehalose and glycogen from external glucose was demonstrated in mycorrhizae-colonized leek roots, and the mycorrhizal symbiosis with roots was shown to be essential to the synthesis. Figure 7 illustrates the synthesis of $\gamma$-aminobutyrate (GAB) from external NH$_4^+$ in carrot cells via the amino acid Glu and possibly Ala. This, together with the intracellular pH data obtained from $^{31}$P-NMR, revealed a significant role of GAB in pH homeostasis in plant cells.

2.1.1.3 Limitations Sensitivity is always a limitation in NMR. This limitation accounts in part for the popularity of high-natural-abundance $^{31}$P-NMR applications and the need for isotopic enrichment for $^{13}$C- and $^{15}$N-NMR applications. In addition, tissue samples, unlike homogeneous solution, disrupt magnetic homogeneity, which degrades sensitivity due to increased line width. This problem particularly affects $^1$H-NMR applications since the $^1$H spectral range is narrow. Moreover, the cytoplasm (where metabolites of interest often reside) of plant cells often occupies only a small fraction of the cell volume, which further adds to the difficulty of detection. On the other hand, a much larger cytoplasmic volume is present in the fast growing regions (root and shoot tips), which explains their popularity for in vivo NMR applications.

There are also constraints on sample size and types depending on the magnet configuration. In general, maximizing sample density is highly desired, which complicates...
the maintenance of tissues in a physiologically stable condition, particularly for whole plants. Another difficulty with whole plant work is localizing signals from different anatomical regions, e.g. root tips versus more mature root regions. For leaf tissues, the air spaces often cause such strong line broadening that vacuum infiltration is needed to obtain usable spectra.

Once usable spectra have been acquired, there are the problems of signal assignment, verification, and quantification, particularly for those metabolites whose signals are sensitive to cellular conditions such as pH, ionic strength, divalent and paramagnetic ions, and viscosity. The assignment problem can be straightforward for $^{31}$P-NMR since the number of metabolites involved is small and their signals are generally sufficiently resolved. The assignment difficulty is perhaps most severe for $^1$H-NMR for the following reasons. Due to

the narrow spectral spread and the higher number of observable metabolites, in vivo $^1$H-NMR spectra are generally more crowded in appearance and assignment based on chemical shifts alone is grossly inadequate. In addition, the water signal is orders of magnitude stronger than metabolite signals, which makes it difficult to suppress, particularly when the signal is broad. However, the new pulsed-field gradient method for solvent suppression may greatly alleviate the latter problem. To overcome the assignment problem, a comprehensive analysis of NMR-observable metabolites in tissue extracts needs to be obtained to assist the in vivo NMR assignment. Despite these shortcomings, $^1$H-NMR remains attractive for its superior sensitivity and high information content.

It should be emphasized that assignment of metabolite signals that arise from different compartments should be independently validated by other analysis. Caution should also be taken in utilizing in vivo NMR signal intensities for absolute quantification, particularly in crowded spectra and when intensities are sensitive to metabolite mobility via binding to membranes or large proteins and to exchange with ligands such as paramagnetic and divalent cations. The latter processes could attenuate or even eliminate metabolite signals.
Signal attenuation by immobilization is substantial for sodium ions while that by exchange with cations is most relevant to phosphate metabolites and organic acids.

2.2 Plant–Soil Interactions

2.2.1 Plant Extract Characterization

In addition to in vivo applications, NMR is eminently suited for profiling metabolites in a wide variety of biological extracts including those of plants, algae, and soil microbes. The NMR analysis has the following unique advantages:

- Molecular structure information can be obtained directly in crude extracts;
- Extensive sample preparation and associated artifacts are eliminated;
- A comprehensive profile of metabolites can be acquired simultaneously with unequivocal structure confirmation;
- Unexpected and/or unknown metabolites can be detected and identified without the need for authentic standards;
- It is vital to a reliable assignment of in vivo NMR resonances.

These advantages of in vitro NMR analysis of tissue extracts have been demonstrated in a number of plant metabolic studies.\(^{(15,25,30,32,30,52–57)}\) For example, not only were a number of amino and organic acids detected in the extract of a euryhaline alga isolated from an agricultural drainage evaporation pond, but two unexpected metabolites (trehalose and dimethylsulfonium propionate) were also revealed by 2-D \(^1\)H-ToCSY analysis (Figure 8).\(^{55}\) The latter two compounds are likely to be involved in the osmotic adjustment in this alga. In another study, the identity of dimethylselenonium propionate and other organoselenium metabolites was unequivocally confirmed in synthetic mixtures without purification by a combination of 2-D \(^1\)H-ToCSY, \(^{77}\)Se–\(^1\)H-heteroCOSY, and \(^1\)H-DQF/COSY (double quantum filtered correlation spectroscopy) analysis. This information was then utilized to determine the identity of selenium metabolites in algal extracts.\(^{(56,57)}\) Moreover, 2-D \(^1\)H-ToCSY, \(^{15}\)N–\(^1\)H-HSQC, and \(^{15}\)N–\(^1\)H-HSQC/TOCSY (Figure 9) experiments were used to determine \(^{15}\)N-labeled metabolites and to estimate the %\(^{15}\)N enrichment in these metabolites in rice coleoptiles in response to a combination of hypoxia, \(^{15}\)N-nitrate, and \(^{15}\)N-ammonium treatments.\(^{(54)}\) Together with the position of the \(^{15}\)N label in each metabolite, different assimilation pathways of nitrate and ammonium ion were uncovered.

2.2.2 Plant Exudate Characterization

The utility of in vitro NMR for tissue metabolite profiling is equally valuable for analyzing exudates excreted by plants and/or microbes. This emerging application holds great promise in advancing our knowledge in plant–soil interactions. This is because exudation accounts for a large organic input to the soil and is intimately involved in a number of important processes such as trace nutrient acquisition, plant–plant interaction, microbe–plant interaction, microbial community, and humification. For example, exudation of phytosiderophores and bacteriosiderophores has been shown to play a vital role in Fe acquisition by plants and soil microbes.\(^{(58)}\) However, a mechanistic understanding on the role of plant and microbe exudates in these processes has been hampered by a general lack of information on the exudate composition. This gap of knowledge has been a difficult challenge to conventional analytical methods but application of NMR to this problem will greatly help to circumvent the difficulty.

This is illustrated in a recent study on a comprehensive analysis of plant root exudates using the multinuclear and 2-D NMR approach.\(^{(59)}\) Three derivatives of mugineic acid (phytosiderophores) were identified and quantified directly in crude barley exudates without fractionation, along with a number of amino and organic acids. The mugineic acids were found to dominate the total organic ligand equivalents in barley exudates only under severe Fe deficiency, while other ligands contributed comparably under less Fe-deficient conditions. This finding may have important implications in agricultural soils where mild Fe deficiency may be most relevant.

2.2.3 Natural Organic Matter Characterization

NOMs represent one of the Earth’s most abundant carbon reserves.\(^{(60)}\) They are composed of compounds with a wide chemical diversity, particularly the humic and fulvic acids (Hayes et al.,\(^{(61)}\) and references therein). Humic/fulvic acids or humates/fulvates (the more likely ionization state in natural soils) are quasi biomacromolecules since they are derived from decomposed plant/algae/animal debris and microbes through complex and yet largely undefined processes\(^{(62,63)}\) which may also involve the mineral matrix.\(^{(64,65)}\) Consequently, humic/fulvic structures are notoriously heterologous and largely non-polymeric\(^{(66)}\) unlike biopolymers such as proteins and nucleic acids. The heterogeneous nature of humates and fulvates has presented a unique challenge to their structural characterization and thus to a mechanistic understanding of their function(s) in the environment. Soil and sediment humates and fulvates are active participants in a number of important processes involving plant/algae/animal debris and microbes through complex and yet largely undefined processes. This is because exudation accounts for a large organic input to the soil and is intimately involved in a number of important processes such as trace nutrient acquisition, plant–plant interaction, microbe–plant interaction, microbial community, and humification. For example, exudation of phytosiderophores has been shown to play a vital role in Fe acquisition by plants and soil microbes. However, a mechanistic understanding of the role of plant and microbe exudates in these processes has been hampered by a general lack of information on the exudate composition. This gap of knowledge has been a difficult challenge to conventional analytical methods but application of NMR to this problem will greatly help to circumvent the difficulty.
Figure 8. 1-D High-resolution and 2-D 1H-TOCSY/NMR spectra of Chlorella algae extracts from control and Se treatments. The 1-D 1H-NMR spectra were obtained from the 100 ppm Se (a) and control (b) treatments while the 2-D 1H-TOCSY spectrum (b, displayed as a contour plot below the corresponding 1-D spectrum) was acquired from the control treatment. Rectangular boxes connect the diagonal to the off-diagonal cross-peaks, which illustrate the 1H scalar coupling network of dimethylsulfoxonium propionate (DMSP), trehalose, and proline. Peak assignment is as follows: 1, βCH₃ of lactate; 2, γCH₃ of Thr; 3, βCH₃ of Ala; 4, 5, 7, 19, γCH₂, βCH, βCH, and αCH of Pro; 6, 8, β and γCH₂ of Glu; 9, 10, α, γ and α'; γ' CH of citrate; 11, 12, 14, αCH₂, S-CH₂, and βCH₂ of DMSP; 13, 18, N-CH₃ and αCH₂ of glycinebetaine; 15, 16, 17, 20, C4H, C2H, C6H, C3, 6H, and C1H of trehalose, respectively. (Reprinted from Fan et al., with permission of American Chemical Society © 1997.)
mineral nutrition, microbial activities and community, pollutant transport and bioavailability.\footnote{67,68} NMR has been applied to NOM characterization for over three decades.\footnote{69} The lack of sensitivity and resolution of earlier NMR instrumentation prevented its routine use in NOM research. However, with the dramatic improvements in NMR technology in the last decade, NMR has emerged as the method of choice for obtaining structure information on soil humates and fulvates. A number of solution- and solid-state NMR methods involving $^1$H, $^{13}$C, $^{31}$P, and $^{15}$N nuclei have been applied to humate and fulvate characterization as a function of soil sources, soil decomposition/development, humification,\footnote{70} cultivation, burning,\footnote{71,72} as well as interactions with xenobiotics\footnote{73} and metals.\footnote{60,65,69,74–76,78} In addition, a few studies have utilized other NMR-active nuclei including $^{27}$Al,\footnote{79} $^{29}$Si,\footnote{80–82} $^{31}$P,\footnote{83} $^{51}$V,\footnote{84} and $^{113}$Cd.\footnote{85–87}

2.2.3.1 $^1$H-Nuclear Magnetic Resonance Despite the high sensitivity of the $^1$H nucleus, few $^1$H-NMR methods have been applied to humic and fulvic characterization compared with $^{13}$C-NMR applications. This is largely because resonances in 1-D $^1$H-NMR spectra of humates are severely overlapped, which limits the structural information obtainable. This spectral overlap results from a
combination of the large number of chemical groups, chemical shift heterogeneity (due to variability in chemical environments of similar groups), the macromolecular size, and paramagnetic broadening. The presence of multivalent paramagnetic ions also limits the solubility of humates in D2O, which necessitates the use of reactive solvents such as d6-dimethylsulfoxide (d6-DMSO) and NaOD.88

To date, most of the 1H-NMR studies have been performed in the liquid state.89–93 This is because in the solid state the strong dipolar coupling between protons leads to very broad lines (ca. 50 kHz) that are difficult to narrow by MAS or other standard techniques.5 This yields poor quality 1H-NMR spectra.88 However, 1H–1H dipolar interactions were exploited in 2-D solid-state 1H-NMR spectroscopy, where dipolar dephasing was varied in the second dimension to obtain dipolar interactions as a function of chemical shift (i.e. different chemical groups).88

The information obtained from 1H-NMR studies of humates includes types of substructures and abundance of a given substructure. A 1-D 1H-NMR spectrum of a sediment humate is shown in Figure 10,90 where the spectral resolution is superior to that commonly obtained for soil humate. Substructures were assigned primarily by 1H chemical shifts and existing knowledge of humate composition. Spin–spin coupling information is typically lost in humate spectra because the peaks are too broad to resolve the spin multiplets. Table 1 lists some 1H chemical shifts and their substructure assignments for different humate preparations. These assignments, although valuable, should be considered tentative since the chemical shift range of various proton groups (e.g. methyl, methylene, methine) depends strongly on their electronic environment and is not sufficiently distinct to allow unequivocal assignment. For example, the chemical shift for methyl protons (<1 ppm) is normally lower than those of methylene and methine protons. However, when the methyl protons are attached to oxygen (i.e. methoxyl), their shifts can reach as high as 3–4 ppm or the methine proton range (Table 1). These ambiguities in chemical shift assignments need to be resolved by other means.

2-D 1H-NMR spectroscopy has a tremendous potential in resolving many of the assignment ambiguities and

in obtaining conformational information, as shown by the numerous 2-D applications in structure/conformation determination of proteins and nucleic acids. To date, only a few 2-D $^1$H-NMR analyses of soil humates and fulvates have been reported. Particularly interesting was the conformational analysis of humate by 2-D $^1$H-NOESY that provided evidence for the presence of two distinct domains: a flexible aliphatic chain and a more condensed aromatic domain. The following 2-D $^1$H-NMR measurements further illustrate the values of 2-D NMR analysis.

Figure 11 shows a total correlation 2-D $^1$H-NMR spectrum as a contour map of a humate preparation extracted from a Sierra Nevada range forest soil (Forbes). As described in section 1.3.1, TOCSY provides information on an intramolecular covalent bond network which is traced by the off-diagonal cross-peaks (noted by rectangular boxes in Figure 11). Consequently, substructure assignments are derived from multiple pieces of information rather than from chemical shift alone. For example, the resonances at 1.38, 1.6, 1.96, 2.28, and 4.31 ppm are correlated through their cross-peaks, which indicates a substructure of $\text{Z-OH}_2-\text{CH}_2-\text{CH}_2-\text{CH}_2-\text{CH-XY}$, where X, Y, and Z could be O, N-containing functional groups or aromatic rings. Also evident in Figure 11 is the presence of similar substructures in slightly different chemical environments. For example, two groups of cross-peaks in the 1.2–1.4 and 4.1–4.4 ppm regions indicate the presence of the $\text{CH}_3-\text{CH-XY}$ structure. The small variation of the chemical shifts in these two regions suggests the presence of different X and/or Y functional groups in the substructure, which is consistent with the heterologous nature of humates.

Other than conformational analysis, 2-D $^1$H-NOESY is useful in probing intermolecular interactions between humates and other ligands since NOE reveals interactions
Figure 12 NMR evidence for the interaction between desferrioxamine B (DFOB) and Forbes humate. (a) 1-D $^1$H-NMR spectrum of DFOB, a common and powerful organic ligand for transition metals in soils. Numbered spectral assignments were based on Borgias et al. (1989). (b) 1-D $^1$H-NMR spectrum of Forbes humate in the presence of excess DFOB. (c) Contour plot of 2-D $^1$H-NOESY of the sample from (b). The corresponding off-diagonal cross-peak pattern for free DFOB, HS, and DFOB + HS is represented by thin dashed lines, thin solid lines, and thick solid lines, respectively. These cross-peaks indicate regions of intra- and intermolecular associations via exchange and dipolar interactions. (Reprinted from Higashi et al., © 1998, with permission of the Royal Society of Chemistry.)

between protons that are within 5 Å apart and/or in chemical exchange (see section 1.3.1). Figure 12 shows a NOESY spectrum as a contour map of Forbes humate (as in Figure 11) in the presence of a powerful bacteriosiderophore DFOB. Also shown are the 1-D spectra of DFOB and DFOB + Forbes humate. Here, the off-diagonal cross-peaks represent dipolar couplings while the diagonal peaks correspond to those in the normal 1-D spectrum. From the NOESY spectrum, dipolar couplings originating from DFOB (dashed line) and humate (solid line) can be traced, most notably from 2.75 to 7.76 and 5.87 ppm for the humate. This proton connectivity is absent in the TOCSY spectrum (data not shown), indicating that the interactions are through space, not via scalar coupling. Thus, NOESY and TOCSY analyses are complementary and together they provide information on primary and higher-order structures of humates. In addition, NOESY cross-peaks reveal complexation of DFOB with humate, as traced by thick solid lines. These cross-peaks are absent in either DFOB or humate spectrum, thus providing unequivocal evidence for the binding of DFOB to Forbes humate. Moreover, the molecular detail of the binding sites can be deduced from the NOESY spectrum, which involves...
the interaction between the diaminopentyl and succinyl protons of DFOB and the aromatic/phenolic and/or saccharidic groups of the humate. The complexation between siderophores (Fe chelators) or other metal ligands and humates is previously unknown and will have significance in metal transport and bioavailability in the soil environment.

2.2.3.2 \( ^{13}\text{C}-\text{Nuclear Magnetic Resonance} \) \( ^{13}\text{C}-\text{NMR} \) and solid-state analysis, in particular, is by far the most prevalent NMR technique employed for NOM characterization. Despite its low sensitivity, \( ^{13}\text{C}-\text{NMR} \) has been preferred over \( ^{1}\text{H}-\text{NMR} \) because of the greater characterization. Despite its low sensitivity, \( ^{13}\text{C}-\text{NMR} \) is the most prevalent NMR technique employed for NOM and solid-state analysis, in particular, is by far the liquid-state \( ^{13}\text{C}-\text{NMR} \) spectra of the same soil fulvate. Solid-state CP/MAS acquisition, together with a shorter interpulse delay practical for in situ soil analysis, can help improve detection sensitivity. Both qualitative and quantitative differences are evident, including different sensitivity, spectral resolution, and relative peak heights. For example, a distinct peak at 211 ppm (often assigned to ketone or aldehydic carbons) in the solid-state spectrum is absent in the liquid-state spectrum. In addition, the relative intensity of the 0–80 ppm region (aliphatic carbons) is lower in the liquid-state than in the solid-state spectrum. These differences may result from the inability of liquid-state measurements to detect more rigid structures, which has been postulated for aliphatic groups in humates. Moreover, the relatively higher intensity of the aromatic region in the liquid-state spectrum may be attributed to a high aromatic substitution which would reduce the efficiency of CP transfer and therefore the \( ^{13}\text{C} \) signal intensity in the solid-state spectrum. Quantitative differences between liquid- and solid-state \( ^{13}\text{C} \) spectra were also observed in another study, although the two spectra were qualitatively similar.

On the other hand, solid-state analysis is not without disadvantages. The analysis may be complicated by the presence of other organic compounds and factors such as the presence of excess paramagnetic ions and degree of protonation in humates. There are also complications associated with the CP/MAS technique. MAS can lead to spinning side bands while CP transfer may result in inconsistent peak quantification among different samples or among various chemical groups of the same sample. This is because peak intensities acquired under the CP transfer mode depend on the optimal contact time, which is known to vary with different humates and their chemical groups. These problems need to be carefully addressed for quantitative analysis of humates by solid-state \( ^{13}\text{C}-\text{NMR} \).

Despite the above limitations, CP/MAS \( ^{13}\text{C}-\text{NMR} \) is presently one of the most popular techniques for determining humate chemical groups and their abundance. Table 2 lists some \( ^{13}\text{C} \) assignments of chemical groups and their abundances in NOM. As is the case for \( ^{1}\text{H}-\text{NMR} \), assignment ambiguities exist for \( ^{13}\text{C}-\text{NMR} \) when based on chemical shift alone. Different approaches have been employed to reduce these ambiguities, including the use of INEPT and dipolar dephasing \( ^{13}\text{C}-\text{NMR} \) spectroscopy. Verification of chemical group assignments by other spectroscopic methods such as infrared spectroscopy and wet chemical analysis has also been utilized.

2.2.3.3 \( ^{15}\text{N}-\text{Nuclear Magnetic Resonance} \) Applications of \( ^{15}\text{N}-\text{NMR} \) in NOM analysis have been limited by experimental difficulties including the low intrinsic sensitivity and natural abundance of the \( ^{15}\text{N} \) nucleus, negative magnetogyric ratios that result in unfavorable NOEs, and long \( T_1 \) values. Inverse-gated decoupling and \( ^{1}\text{H} \) to \( ^{15}\text{N} \) polarization transfer (e.g. INEPT), and acoustic methods have been employed to eliminate the problems.

M = major; S = significant; T = trace.

(e.g. $^{15}$N-ammonium compounds, $^{15}$N-nitrate, and $^{15}$N-amino acids, and $^{15}$N-herbicides) has been used. Such manipulation not only allowed usable $^{15}$N-NMR spectra to be obtained but more importantly it revealed the molecular mechanism(s) of NOM interaction with herbicides,$^{107}$ and NOM’s role in nitrogen fertilizer,$^{108,109}$ nitrification/denitrification processes,$^{76,77}$ and transport of aquatic pollutants.$^{110}$ A number of N-containing
functional groups have been assigned in NOM that were derived from $^{15}$N-labeled fertilizers, amino acids, and herbicides (Table 3, adapted from Steelink$^{106}$). Again, these assignments were mainly based on chemical shifts, which would need verification since $^{15}$N chemical shifts are highly sensitive to solvent polarity, pH, presence of paramagnetic ions, and ionic strength.

2.2.3.4 $^{31}$P-Nuclear Magnetic Resonance The application of $^{31}$P-NMR to NOM analysis was initiated in the early 1980s$^{74}$ and subsequently several studies on soils$^{111}$ compost, and sewage sludge$^{83,97}$ have been reported. Example $^{31}$P-NMR spectra of humates are shown in Figure 15, where phosphonates, inorganic orthophosphate, inositol hexaphosphate, phosphate monoester, aromatic phosphate diester and nucleic acid, and phosphate diester were assigned$^{111}$ Also evident in Figure 15 is the dependence of the $^{31}$P profile on the molecular size fraction of humates. Variable $^{31}$P profiles were also observed with different cultivation and fertilization history. These studies demonstrate some of the potential values of $^{31}$P-NMR in probing NOM structures.

However, there has been relatively little method development in $^{31}$P-NMR for NOM analysis. Two major issues need to be resolved, i.e. validation of chemical-shift-based resonance assignment (since $^{31}$P chemical shifts are highly dependent on pH, ionic strength, and paramagnetic ions) and quantitative reliability. The latter issue would require systematic studies on extraction recovery of phosphate functional groups (particularly under alkaline conditions), $^{31}$P relaxation properties, and NMR “visibility” of different $^{31}$P signals. Since phosphates have a high affinity towards multivalent cations, the presence of these ions (particularly paramagnetic ions) can significantly affect the line widths of different phosphate signals, and therefore their peak intensities. For quantitative analysis it is necessary to adopt procedures that remove these ions.

2.2.3.5 Other Nuclei Although potentially powerful, there have been few applications of other NMR nuclei to NOM analysis, most likely due to the low concentration and a general lack of knowledge of these nuclei in NOM. In two related studies,$^{27}$$^{29}$Al- and $^{29}$Si-NMR was employed to examine the aluminum and silicon–oxygen coordination chemistry in soils and clay fractions. $^{75,80}$$^{29}$Si-NMR was also applied to analyze for carboxylic, phenolic, and alcoholic groups in silylated humates. $^{82}$ In a $^{51}$V-NMR study, vanadate reduction and subsequent speciation in the presence of aquatic humates was reported.$^{84}$$^{113}$Cd-NMR was employed to probe complexation of Cd$^{2+}$ with NOM and provided valuable evidence for Cd$^{2+}$ coordination with the oxygen and nitrogen donors of NOM. $^{85}$ With the dramatic improvement in NMR technology and increasing knowledge of NOM structures, it is foreseeable that nuclei other than $^{13}$C, $^{1}$H, $^{15}$N, and $^{31}$P may receive increasing attention.

3 FUTURE PROSPECTS

3.1 Resolution

For aqueous biological extracts, a large number of compounds can be resolved and identified simultaneously by 2-D NMR such as TOCSY (see above). However, in the sugar region (3.2–4.7 ppm), only a few of the common mono and disaccharides are discernible because of the severe spectral overlap in this region. Resolution can be improved with increasing magnetic field strength, e.g. from low hundred MHz to 800 MHz or 900 MHz, which
is to become available in the near future. However, these ultrahigh field instruments are access limited and the improvement in resolution is modest. A more effective means for improving resolution is to add extra frequency dimensions to NMR experiments. It is now feasible to conduct homonuclear 3-D NMR experiments, such as TOCSY/TOCSY or TOCSY/ROESY, although they are more acquisition time-consuming (e.g. 3 days) and the spectral analysis is more complicated. An alternative to homonuclear 3-D NMR is the heteronuclear approach, e.g. combining TOCSY with HSQC. Here the low natural abundance of $^{13}$C and $^{15}$N can be a limitation. However, they should be extremely valuable for the analysis of isotopically enriched metabolites.

3.2 Detection Limits

The NMR sensitivity is a function of the instrument hardware and the sample, with the two often interactive. The hardware is continuously improving, e.g. higher magnetic field strength, higher signal-to-noise amplifiers, and improved probe design. Higher sensitivity can also be attained by increasing sample size and/or concentration in the detection region. The standard NMR probe accepts 5-mm diameter tubes, which readily gives a good line shape and good matching and tuning for optimal sensitivity. Larger diameter probes often yield poorer sensitivity due to nonoptimal line shapes and tuning. With improved probe design, the sample size can be increased (e.g. to 8 mm diameter) without compromising line shape and tunability, such that the expected gain (e.g. 2.5-fold compared with 5-mm diameter size) is obtained. When the amount of sample is limited, higher sample concentrations (e.g. twofold) can be obtained by restricting the active volume with doped glasses that match the magnetic susceptibility of the solvent (e.g. Shigemi tubes). Moreover, the advent of pulsed field gradient methods affords much better solvent suppression capability and flexibility in multidimensional NMR experiments, both contributing to better detection limits.

3.3 New Applications

The majority of NMR applications in agriculture have been in the area of chemical identification. As NMR is also a powerful technique for probing molecular dynamics and conformation, applications along these areas should prove to be very fruitful. From the few studies available in the literature,$^{12,85}$ the use of NMR analysis for metal speciation and organometallic chemistry, exchange dynamics between ligands and NOM, and NOM conformation and binding site characterization is expected to break exciting new ground in the understanding of plant–soil interactions.

Nuclear magnetic resonance (NMR) is an experimental technique based on the interaction between an applied magnetic field and nuclear magnetic moments in a sample. NMR provides information on material composition, molecular structure, physical structure, physical properties and dynamics of phase changes. NMR is a noncontacting and noninvasive measurement. NMR has been used for the routine analysis of foodstuffs and plant materials. NMR is used in the analysis of foods to detect moisture content, solid/liquid ratio in fats, adulteration of juices and characterization of texture. Applications of NMR to plant materials include observation and characterization of metabolites and ions, determination of pH and following changes of these over time. NMR is also used to determine structures of natural products isolated from plants. Magnetic resonance imaging (MRI) is used in both foodstuffs and plant materials to study morphology and also water transport, diffusion and variations of these under different conditions. The response of NMR is linear from the detection limits of approximately 10 ppb to 100%. The accuracy of the technique depends upon the signal-to-noise ratio (S/N), which is a function of the sample size, applied magnetic field strength, the radiofrequency (RF) coil, the spectrometer hardware and experimental parameters. Typical accuracy is 0.5% for composition and 1–5% for viscosity.

1 INTRODUCTION

NMR analytical applications in food and plant materials are extensive. The applications range from simple determinations of water content to the determination of molecular structure of compounds and the internal physical structure of the material. The focus within this article is on both standard techniques and emerging techniques. Low-resolution nuclear magnetic resonance (LRNMR) has been used extensively in quality assurance laboratories to measure average sample properties such as fat content and water droplet size distributions. More recently high-resolution and multidimensional experiments have been applied to characterize composition, authenticate the material, measure the internal physical structure and characterize component interactions and functions.

NMR has several advantages as an analytical technique; these include minimal sample preparation, rapid analysis and the potential to run multiple tests on a single sample. To date, primarily LRNMR and NMR spectroscopy have been used in analytical laboratories; however, recent advances in automating experiment set-up and operation coupled with the development of new methods indicate expansion of the use of NMR spectroscopy and the beginning of the application of imaging systems in analytical settings.

2 HISTORY

The initial successful NMR experiments were performed in the laboratories of F. Bloch and E. Purcell. The discovery of the chemical shift permitted the expansion to chemical applications. The use of NMR in the analysis of chemical and biochemical molecules is an essential tool in research and more recently in analytical laboratories.
Advances in fields other than food technology have provided NMR spectroscopists with the ability to improve dramatically both experiments and data analysis. In the area of magnet design, advances enabling very high magnetic field systems have allowed NMR to be used to study the fine detail of molecular structure. Advances in computer technology coupled with digital fast Fourier transforms have permitted the development of multidimensional NMR methods.\(^{4−6}\) Occurring simultaneously with the development of multidimensional NMR was the technique of generating images of the internal structure of materials.\(^ {7,8}\) Called NMR imaging or MRI, this technique has been primarily developed as a standard radiological diagnostic method.

Use of NMR for routine analytical testing has primarily focused on the use of low-resolution systems to measure sample composition (e.g. moisture content, fat content or polymer content) and/or physical state of the sample (e.g. solid-fat to liquid-fat ratio). These applications are prevalent in the chemical, agricultural, food and medical industries. One of the oldest applications, the use of LRNMR to measure the solid-to-liquid ratio in cocoa butter in chocolate manufacture, was implemented during the 1960s.

### 3 INSTRUMENTATION

NMR instrumentation used for analytical purposes is based on similar components. Each spectrometer will consist of a magnet, an RF network, amplifiers, a low-noise receiver, an RF coil, a pulse programmer and a computer system for data analysis and system control. These spectrometers can be classified broadly by placing them in categories of low-resolution, high-resolution and MRI analysis. The differentiation between these categories is not distinct and often an NMR spectrometer may be classified in two of the categories, by its use and by its operational characteristics. This distinction between the spectrometers is both in terms of the experiments performed on the system and the magnetic field strength and RF network.

#### 3.1 Low-resolution Analysis

LRNMR spectrometers utilize a low-field permanent magnet to generate the magnetic field. The range of magnetic field strength is 0.1–0.65 T (4.3–27.7 MHz proton frequency). The analysis of the NMR signal is performed in the time domain. The characteristics of the signal that are used for analysis are as follows:

1. The initial amplitude of the signal is directly proportional to the total number of protons in the sample.
2. The proton signal is a superposition of the signals from all proton-containing components.

3. Separation of the signals from different components is based on differences in relaxation rates between different components.

Low-resolution system costs are relatively inexpensive compared with high-resolution systems/MRI spectrometers. The range of cost is typically between $20,000 and $150,000, the difference being the accessories ordered with the basic system. Available accessories include pulsed-field-gradient units and temperature-controlled probes. The instruments have been designed specifically for routine analysis and to achieve a high degree of accuracy and reproducibility.

#### 3.2 High-resolution Analysis

The major differences between low-resolution and high-resolution nuclear magnetic resonance (HRNMR) spectrometers are the properties of the magnet and the use of frequency domain analysis. For high-resolution spectrometers, the main magnetic field is significantly stronger than for low-resolution systems. High-resolution spectrometers utilize a magnet with field strengths normally ranging from 7 to 14 T. Costs of complete systems in this field strength range are typically $300,000–$800,000.

A high-resolution experiment differentiates between nuclei in one molecular environment and another based on differences in nuclear resonance frequency. Differences in the frequency result from variation in structure and the local chemical and electronic environment for each nucleus. The frequency of excitation (\(v\)) for each nucleus is proportional to the magnetic field at the site of that nucleus. The differences in frequency are described by Equation (1):

\[
v = \frac{\gamma B_0 (1 - \sigma)}{2\pi}
\]

where \(v\) is the nuclear resonance or Larmor frequency in megahertz, \(B_0\) is the magnetic field strength, \(\sigma\) is the shielding constant and \(\gamma\) is the gyromagnetic ratio. Values of the shielding constant range between \(10^{-3}\) and \(10^{-6}\) for most nuclei.\(^{9}\) Equation (1) demonstrates the importance of increasing the field strength, since the actual frequency separation is proportional to the static magnetic field strength.

For many complex mixtures and systems with small variations in shielding constants, multidimensional (N-dimensional, where \(N\) generally is 2 but also sometimes 3 or even 4) experiments are used. Multidimensional experiments generate spectral data that are a function of two or more independent variables. Common two-dimensional (2-D) experiments include such independent variable pairs as chemical shift vs scalar couplings and chemical shift vs dipolar couplings. Data in \(N\)-dimensional experiments are collected with \(N\) time domains and subjected to
Fourier transforms to produce $N$ axes in the frequency domain.

### 3.3 Magnetic Resonance Imaging Analysis

MRI experiments can be considered a subset of multidimensional HRNMR experiments. In MRI the independent variable pairs most often relate directly to spatial locations and hence a spatial map of signal intensity is recorded. The additional hardware to permit this spatial localization is the use of pulsed linear magnetic field gradients. The effect of the linear magnetic field gradients is to make the frequency of the spin proportional to its spatial location. The frequency variation developed by the pulsed linear magnetic field gradient must be greater than other sources of frequency variation in the sample (e.g. chemical shift and line broadening).

### 4 FOODSTUFFS

#### 4.1 Laboratory Quality Assurance

LRNMR has become a standard instrument for use in laboratory quality assurance of fats and oils and for determining the composition of oil seeds. Methods employing NMR have been standardized and approved by the American Oil Chemists’ Society (AOCS) (AOCSd 16b-93, AOCS Ak 4-95), the International Union of Pure and Applied Chemistry (IUPAC) (solid fat content, IUPAC Norm 2.150) and the International Standards Organization (ISO) (oil seeds, ISO Dis/10565, ISO CD 10632). Additional quality assurance applications of LRNMR are listed in Table 1. The detection limits for LRNMR are a few hundred parts per million for hydrogen and fluorine nuclei. Most low-resolution experiments are based on using a ratio of the signal intensity from two different points in time during the free induction decay (FID) or on the multipoint analysis of the time decay of the signal.

Solid fat content measurements are one of the most successful applications of LRNMR. This measurement can be implemented in a variety of ways with LRNMR. The most common is the direct method that relies on the ratio of NMR signal amplitude at two times during the FID. Figure 1 shows the time evolution of the signal in a direct determination of the solid fat content. The sample of fat is tempered prior to being placed in the NMR spectrometer. After placement in the magnet the sample is permitted to achieve equilibrium which commonly takes between 2 and 6s. A single RF pulse is applied to the sample and the signal is recorded. The intensity of the signal immediately after the RF pulse is a measure of the total number of protons in the sample and is proportional to the solid plus the liquid protons. The protons in the solid phase of the fat decay much faster than the protons from the liquid phase. This permits the signal from the two phases to be separated by the difference in rates of signal decay. The signal intensity measured after the decay of the solid signal is proportional to the liquid-phase protons only. The intensity of the liquid-phase protons recorded at 70$\,\mu$s is unaffected by the slight time delay. For example, the $T_2$ of liquid oils is approximately 100 ms, so the signal recorded at 70$\,\mu$s is reduced in intensity by less than 0.1% from the initial value.

In practice, the signal immediately after the RF pulse is not recorded for 7–10$\,\mu$s, because the receiver network of the NMR spectrometer requires time for recovery from the intense RF radiation during the excitation pulse. This recovery time is referred to as the dead time. This dead time is a significant part of the decay of the proton signal from the solid fat fraction. The influence of the dead time on the solid-phase determination is corrected for by using

#### Figure 1

Signal decay from an LRNMR spectrometer.
a factor commonly called the “f factor”. It is assumed that the solid signal immediately after the RF pulse is directly proportional to the f factor times the solid signal following the dead time (Equation 2):

\[ S_s(0\mu s) = fS_s(10\mu s) \]  

The fraction of solid phase is then calculated by Equation (3):

\[ \text{solid phase fraction} = \frac{fS_s(10\mu s)}{S_s(70\mu s) + fS_s(10\mu s)} \]  

The numerical value of f will depend upon the duration of the dead time and the decay rate of the solid-phase protons. The correction factor is determined using standard oil samples. Ideally the correction factor should be close to unity.

Critical to the success of measuring the solid fat content is the temperature history of the sample prior to measurement. The temperature control of the tempering block used to hold the sample prior to measurement should be at least 0.1 °C. It should be noted that the measurement temperature in most LRNMR systems is 40 °C and hence the oil sample should not be kept in the magnet for more than 10 s. After 10 s in the LRNMR spectrometer the solid phase will begin to melt.

The method described above is commonly referred to as the direct method. This is considered the fastest, simplest and most convenient technique. The reproducibility of the direct method is 0.4%. Other methods employ either a variation of the direct method or curve deconvolution of a complete magnetization decay curve. There are many other LRNMR applications for quality assurance and some common examples are listed in Table 1. Detailed descriptions of these techniques can be found in Bruker Application Notes. An introduction to the most common methods was given by Barker and Stronks.

The most recent developments in LRNMR applications are the extension of these techniques to include particle size measurements and measurements of 19F content.

### 4.2 Soluble Components

High-field studies (500 MHz or greater proton resonance frequency) have proven to be very important in the analysis of chemical and biochemical structures in solution. Indeed, high-field spectrometers dedicated to molecular solution structure of species from small organic molecules to biological macromolecules are a standard part of the landscape of universities and major private companies. The advantage of high-field spectrometers is the good dispersion and very high S/N. An additional advantage is a very high dynamic range that permits the characterization of molecules with both strong and weak signals at the same time. Applications in food analyses include improving the understanding of ripening in fruits, characterizing the role of fungal and microbial contamination in fruits and juices and authentication of fruit juices. Shown in Figure 2 are one-dimensional (1-D) proton spectra from different apple varieties.

Even with high-field spectrometers the 1-D spectra of plant extracts will contain many overlapping lines. There are several solutions to this problem. One is to utilize multidimensional techniques to resolve separate sets of resonances for each species present in solution. Another is to use a combination of liquid chromatography (LC) and NMR (LC/NMR) to separate the species chemically before spectra are recorded. Useful experiments for detection of specific compounds by NMR are proton homonuclear correlation “through-bond” pulse sequences such as correlation spectroscopy (COSY) and total correlation spectroscopy (TOCSY). Also important are one bond inverse proton–carbon correlation methods such as heteronuclear multiple quantum coherence (HMQC) spectroscopy.

**Figure 2** Partial spectra of seven different varieties of apple juices. (Reproduced by permission of Aspen Publishers from P.S. Belton, I. Delgadillo, A.M. Gil, *Semin. Food Anal.*, 3, 223–234 (1998).)
and heteronuclear single quantum coherence (HSQC) spectroscopy. LC/NMR is a new and developing method of analysis in which NMR is used as the detector following LC separation. This technique has been used to detect and identify flavanoids in fruit juices and to characterize sugars in wine. The technique is capable of detecting quantities in the lower nanogram range using specially designed flow probes and multiple solvent suppression routines.

Another emerging method is the use of high-resolution magic-angle spinning (HRMAS) to reduce or eliminate the dipolar broadening. The samples are spun at an angle of $54°$ relative to the magnetic axis at speeds between 3 and 15 kHz. This spinning reduces or eliminates the broadening and permits the acquisition of liquid-like spectra in one or two dimensions. These techniques have been used to study wheat proteins and to identify taste-determining compounds in cheese.

4.3 Water

The state of water in foods has been a matter of controversy for many years. The goal has been to derive correlations between water mobility and biological activity and/or food quality. Characterizing the properties of water in a complex and heterogeneous environment such as foods has proven to be very difficult. An approach that has been attempted many times is to measure the relaxation properties (spin–lattice relaxation time, $T_1$, and spin–spin relaxation time, $T_2$) of water and use these to characterize the mobility of water. In general, these approaches have not met with significant success due to the complexity of the relaxation mechanisms.

There are many factors which influence the relaxation times of water protons in foods, including intermolecular interactions between protons on different water molecules, intramolecular interactions between two protons on one water molecule, interactions between a water proton and a proton on a macromolecule and exchange between a water proton and a proton bound to a macromolecule. A simple model for a two-state macromolecular hydration exchange is shown in Figure 3. The model assumes that one layer of “bound” water with a more rapid relaxation rate is in fast exchange with the remaining water which has properties like those of “free” water. This appears to be a reasonable model for protein solutions with more than 50% water. If the water content is reduced below 50% then there are more than two types of water and the range of relaxation times can be very broad. Recent work has shown that it is most often sufficient to model water behavior with three states in biopolymer systems and biological tissues.

4.4 Adulteration and Identification

During the 1980s and 1990s, new analytical methods based on NMR and mass spectrometry (MS) were developed to detect food adulteration. Results from MS give average isotope ratios for the entire sample, e.g. $^{13}$C/$^{12}$C or $^2$H/$^1$H ratios. These ratios can indicate food adulteration; however, this method can be circumvented by isotopic adjustment through addition of a synthetic to the food. The utilization of NMR isotopic analysis has the advantage of a multiisotopic characterization that is more difficult to simulate than an overall isotope ratio. This type of NMR analysis is called SNIF-NMR® (site-specific natural isotope fractionation studied by nuclear magnetic resonance). SNIF-NMR® has been applied primarily to determine whether foods such as fruit juices, flavors, syrup, honey, wines or liquor have been adulterated or inappropriately labeled.
Important atoms with stable isotopes for analyses of food materials are hydrogen, oxygen and carbon. These isotopes occur in specific proportions, e.g. in the case of hydrogen \(^1\)H is 99.985% and \(^2\)H is 0.015% abundant (\(^3\)H is essentially nonexistent in nature). The isotopic content of natural molecules will vary based on the photosynthetic metabolism of the plant and on geographical and climatic conditions. The average value of deuterium in water is 150 ppm, yet specific concentrations depend on location. The concentration of deuterium in water at the earth’s poles, for example, is approximately 70 ppm.

Water is an important reactant in many metabolic processes in plants. The plant will absorb water from the environment and utilize the water to form proteins, sugars and other metabolites. Each plant species will have specific reaction pathways to produce molecules, and different plants will produce the same natural chemicals from different pathways. Hence the combination of different sources of water and different biochemical pathways results in different distributions of deuterium in the molecule that each plant produces. Consider orange juice and beet juice. Each plant makes sugar yet the SNIF-NMR\(^\text{®}\) hydrogen value for sugar from oranges is different than that from beets. Hence the adulteration of orange juice using beet sugar can be detected.

4.5 Structure and Texture

The size of structural components and their spatial distribution in a processed food are important quality attributes that can be measured using NMR and MRI. The range of length scales accessible with NMR is from the molecular level to the size of the food product itself. Standard MRI protocols can be used to measure the distribution of fat, sugar and water. An MRI image of a rice pudding is shown in Figure 4. The change in moisture content and incompletely hydrated rice grains are clearly distinguished. Structure on the scale of an emulsion droplet can be measured using pulsed-field-gradient nuclear magnetic resonance (PFGNMR) spectroscopy, an experiment designed to measure the self-diffusion of molecules. HRNMR or relaxation time studies can be used to characterize the structure on a molecular level. These features allow the use of NMR techniques to characterize structure in almost all types of food products.

Studies using MRI to characterize the sample on a visual length scale include the determination of defects in cheeses. The size, distribution and shape of the eyes in Swiss-style cheese have been measured using MRI proton images analyzed using standard image processing techniques. All physical features of the cheese were graded according to United States Department of Agriculture (USDA) standards. However, quality factors associated with visual perception such as dullness or color could not be graded using MRI. PFGNMR is used to measure the droplet size distribution in food emulsions such as margarine. The procedure is suitable for use both in the laboratory and at a process line. When a system has a heterogeneous structure, the translational motion of diffusing molecules is strongly influenced by the internal structure of the sample. In a confined geometry, the maximum extent of diffusional displacement is limited by the size of the confinement. For example, the diffusion of oil molecules within an emulsion droplet is restricted by the geometry and the dimensions of the internal droplet boundaries. This effect is referred to as “restricted diffusion”. Analysis of the signal decay in a PFGNMR experiment can provide a measure of the characteristic dimensions of the confinement geometry. One of the most common uses of PFGNMR is to measure the size distribution of water droplets in margarine. When this technique is applied to liquid emulsions the temperature of the emulsion may need to be controlled to eliminate the effects of molecules diffusing between droplets.

4.6 Physical and Transport Properties

MRI data can be used to investigate the dynamics of a food process or to calculate physical properties. A variety of food processing operations have been investigated using MRI, including freezing of potatoes, rehydration of pasta, extrusion processing and baking of cookies (Table 2). A comprehensive review and discussion on the use of MRI applied to food processing can be found in books by Hills and McCarthy.

The characterization of physical and transport properties using MRI differs in a fundamental manner from traditional analysis techniques. Most traditional methods employed to measure physical or transport properties rely on an integral approach. For example, classical characterizations of moisture transport in food systems have employed integral techniques such as sorption–desorption or gravimetric methods. MRI provides measurements of component saturations and material properties on a spatially resolved basis. Therefore, instead of an average moisture content for an entire sample, MRI provides the moisture content as a function of spatial coordinates within the object. This permits the calculation of the transport coefficients and the spatial variation of the transport coefficients and also the simultaneous determination of material properties such as membrane permeability.

MRI has provided novel insights into the interaction between products and process equipment. In rotating geometries modeling a couette cell, a scraped surface heat exchanger and a single screw extruder, the velocity and concentration profiles of solid suspensions were measured using MRI. Particle migration was observed to be a function of the geometry of the equipment and the particle migration was sufficient enough to significantly change the local viscosity of the suspension. Corbett et al. concluded that particle migration was best controlled by changes in the geometry of the processing equipment and not by changes in the operating conditions.

4.7 Functional Imaging

Functional magnetic resonance imaging (fMRI) is an experimental technique used to relate sensory perception and/or cognitive activity of the brain to specific locations in the brain. Brain functions associated with visual, auditory and motional activities are actively being investigated using fMRI. These studies have been successful in isolating regions of the human brain that are activated by certain visual and auditory stimuli or tasks. Recently, studies of human taste perception have been initiated.

Locations in the brain activated by six different taste stimuli were identified surrounding and buried in the Sylvian fissure: the upper portion of the insula, the frontal operculum and the pre- and postcentral gyri.

Locations of brain activity are mapped by measuring the associated signal intensity changes in a subject’s MRI images. The MRI images are taken very rapidly, of the order of 2–3 s for the entire brain. One of the rapid MRI techniques such as echo planar imaging or spiral imaging is applied. The change in signal intensity between images, several seconds apart, is a result of a rapid momentary increase in blood flow. For example, when a subject moves the index finger there is a rapid momentary increase in the cerebral blood flow in the specific region of the brain controlling the movement of the finger. The increase in blood flow results in a stronger MRI signal intensity at the specific location of the increase in blood flow. The tissue has a net increase in intravascular oxyhemoglobin and a decrease in deoxyhemoglobin. Deoxyhemoglobin is paramagnetic and hence tissues with a greater deoxyhemoglobin content have a faster decaying MRI signal. The change in signal intensity is between 1 and 5% of the total signal on a 1.5-T medical MRI scanner. Statistical techniques are employed to analyze the changes in signal intensity in fMRI data.

fMRI studies will prove valuable in improving the understanding of the sensory perception of foods. This approach should improve the development of new foods and help in the understanding of sensory methods for the analysis of foods. fMRI has recently been extended to include monitoring and mapping the dynamics of metabolism. Understanding of metabolism and the influence of specific foods on metabolism should play an important role in the understanding of many foods, including nutraceuticals. The development of instrumental methods to replace human sensory studies should benefit from the knowledge gained in these investigations.

5 PLANT MATERIALS

5.1 Introduction

NMR investigation of the vast area of plants can largely be divided into those studies using NMR spectroscopy and those utilizing NMR imaging, MRI. Hence we shall commence with an overview of both MRI and spectroscopy applied to plants, and then consider what information each method provides. There is also a short summary of the analysis of plant natural product extracts. While the literature on plant NMR is not as large as that on medical MRI or liquid spectroscopy of biomolecules, it is nonetheless extensive. We make no attempts to review the field (excellent reviews will cited), but in keeping with the focus of this work instead will give an overview of the field with representative examples to indicate to the interested experimentalist the information...
to be gained by such a study, its advantages and its drawbacks.

A rough distinction between a plant and a plant-derived food (treated in the previous section) is that the former is obviously a living organism, and much of the interest in NMR of plants centers around the noninvasive nature of the technique for studying living plants. With NMR, repeated studies of (for example) a developing fruit or seedling are possible over an extensive course of time. NMR also offers the possibility of defining both molecular metabolic processes via in vivo spectroscopy and “supramolecular” structure or morphology via MRI. To date, most NMR studies have utilized either MRI or spectroscopy, although a few “image-guided” localized spectroscopy studies akin to work in the biomedical field have been reported (see below). The distinction between molecular (spectroscopy) and morphology (MRI) is somewhat blurred since MRI can be used to follow “molecular” processes such as diffusion and nuclear relaxation, which are critically dependent on molecular motion. However, in general, spectroscopy of plants is applied to the observation of metabolites and ions, determination of intracellular pH and the possible variation of these over time under differing experimental conditions. MRI of plants in general concerns itself with morphology, as well as water transport, diffusion and relaxation, including possible variations of these over time under differing conditions.

5.2 Magnetic Resonance Imaging of Plants

5.2.1 Sample Preparation

In practice, MRI studies of plants are almost invariably concerned with a single component of the plant. Sample preparation varies according to the material studied, with fruits, stems, seeds, leaves and nuts generally being easily investigated by simply placing the sample in the magnet. Light and cooling/warming air can easily be introduced into the magnet; generally, complex perfusion systems are the province of plant NMR spectroscopy (see below). With roots in situ both the roots and soil must be placed in the magnet.

5.2.2 Magnetic Resonance Imaging of Plants. What is Observed?

The first point to consider in an examination of (for example) a fruit by MRI is that what is seen is critically dependent on the instrumental conditions, both the hardware used (field strength, shielded vs unshielded gradients, etc.) and the parameters used in the imaging pulse sequence utilized. This point is illustrated in Figure 5(a–d), which shows a single slice through a potato using different imaging sequences. MRI of plants has almost exclusively been devoted to studies using \(^1\)H, hence the proton images in Figure 5(a–d) constitute a map of mobile water protons (the dominant source of proton signal) weighted by their nuclear relaxation times and diffusivity. Use of gradient-echo sequences, choice of \(T_2\) and/or \(T_1\) weighting and use of diffusion weighting are all examples of the choices available to the experimentalist to emphasize different structures within the plant and alter image contrast. The oft-cited simplistic example of an MRI image as a “picture” taken of an object must be viewed with caution in the light of these factors. Nonetheless, the studies cited below indicate that first and foremost MRI can give excellent images of the morphology of a plant noninvasively, i.e. without the excising, fixing and staining necessary for optical images. The resolution with a conventional gradient set strength of 1–10 G cm\(^{-1}\) is roughly about 100\(\mu\)m for a 1-mm thick slice for an acquisition time of a few minutes on a small object (e.g. plant stem, grape), or about 200\(\mu\)m for a 2-mm slice of a larger object (e.g. potato, apple). With microimaging gradient sets (gradient strength 50–100 G cm\(^{-1}\)) the resolution can reach <10 \(\mu\)m in-plane with a 250-\(\mu\)m slice thickness. The small number of nuclei generating observable signals in such a small volume leads to increased acquisition times, of the order of 1 h. Rapid acquisition methods such as echo-planar imaging (EPI), gradient-recalled echo in the steady state (GRESS) imaging and the related fast low-angle shot (FLASH) techniques can dramatically reduce total imaging times by increasing the repetition rate of the pulse sequence, but are limited in their utility in many plants by large susceptibility differences between cells and intracellular air spaces.\(^{47}\) A key distinction for MRI of plants compared with other biological systems. These widespread local susceptibility differences cause a spread in Larmor frequencies leading to loss of resolution and image intensity, especially for sequences (GRESS, FLASH, EPI) that do not utilize spin-echoes. Susceptibility effects increase with \(B_0\) and reduce the sensitivity advantage gained by going to higher fields.\(^{48}\)

In addition to the inherent noninvasive nature of MRI, an additional advantage is that a single image slice can be taken in any direction or (at the cost of increased acquisition time) an entire three-dimensional (3-D) image of an object can be obtained and any desired slice (including user-defined oblique) can be reconstructed from the data analysis. Other advantages of the NMR method are the possibility of choosing chemical shift imaging (CSI) to select sugar or oil protons rather than water, thus mapping the location of those components in the plant. Finally, diffusion-weighted sequences allow the probing of molecular self-diffusion or flow in the plant. Examples of all these studies follow.
5.2.3 Disadvantages of Magnetic Resonance Imaging

Having indicated the utility of plant MRI, what are the disadvantages? First, the resolution generally does not compare with optical or electron microscopy. The cost of an MRI scanner dwarfs that of an optical microscope, although steps to reduce system cost while retaining utility for plant studies are under way. Studies on development of growing plants are not optimally conducted on the prevalent horizontal bore imagers owing to the sensitivity of most plants to the direction of gravity. Vertical bore spectrometers are not optimally configured for plant study, being of narrower bore and usually having difficult access through the bottom. Finally, to date, plant imaging has a far from comprehensive database to guide new studies, and questions have arisen of the biological relevance of the NMR data.

5.2.4 Fruits and Vegetables

We have divided MRI of plants into subsections of fruits and vegetables, stems and roots, along with consideration of single-cell imaging. MRI studies of fruits and vegetables have been relatively extensive. Primary areas of study include quality control, developmental studies and visualization of disease and infestation.  

5.2.4.1 Quality Control; Maturation  

In this area are studies to examine noninvasively internal structure to determine fruit quality in response to storage, ripening, freezing, bruising and disease. An early study used MRI to detect core breakdown in pear. Chen et al. used MRI to examine bruising defects in apple, peach, pear and onion, and also the presence of voids and seeds. The same report showed that MRI could be used to follow ripening in pineapple, tomato and avocado. Core breakdown in pears after storage and then ripening could be determined by spin-echo MRI. Bruising leading to large changes in $T_2$ could be detected in strawberries. Metabolic or physiological disorders detected by MRI in stored fruit include woolly breakdown in nectarines and dry sacks in oranges. Browning disorder has recently been detected using MRI by Clark and Burmeister.
Figure 6 Progression of freezing in a median longitudinal slice of kiwifruit monitored by spin-echo imaging (resolution 390 μm, recycle time = 1000 ms, echo time = 25 ms) at the indicated time points. Freezing was induced by suspending fruit in flowing air at –40 °C in a chamber prior to placing samples in the magnet. (Reproduced from W.L. Kerr, C.J. Clark, M.J. McCarthy, J. de Ropp, ‘Freezing Effects in Fruit Tissue of Kiwifruit Observed by Magnetic Resonance Imaging’, Sci. Hort., 69, 169–179 (1997), Copyright 1997, with permission from Elsevier Science.)

Fruit ripening has been successfully followed in tomatoes and in peaches, nectarines and plums. Some investigators have noted $T_1$ and $T_2$ variations of water with ripening but the results did not show a clear trend among all species. Freezing can cause severe damage to fruits. Freezing usually releases bound water from damaged cells, resulting in increased $T_2$ and brighter image intensity in affected areas. Freezing and chill injury changes have been noted for kiwifruit, blueberries and zucchini.

5.2.4.2 Disease and Infestation

An obvious use of MRI would be in the detection of disease and (insect) infestation in fruit, and indeed many such studies have been conducted. Prominent among these are studies of the progression of fungal infections in fruit. A variety of fruits and infectious fungi have been studied. Raspberry and blackcurrant infection by Botrytis cinerea was elucidated by Williamson et al. using GRESS methodology. The spread of infection in raspberries produced a clean boundary in the image of the fruit. Strawberries infected with different pathogens produced different images, suggesting that differentiation of infectious agents may be possible by MRI. Similar results were obtained for two different pathogens of potatoes. Mazucco et al. have shown images clearly identifying fruit fly larvae in mangoes.

5.2.5 Stems

The cylindrical symmetry of stems makes them ideal candidates for transverse imaging over a relatively thick slice by MRI (Figure 7a and b). MRI studies of plant items have been used for a variety of purposes; one of the most notable is the investigation of water flow within the stem. The rate and start of rehydration after water stress in Blechnum unilaterale stems have been examined; both proton density and $T_1$ values altered with dehydration/rehydration. Johnson et al. observed changes in water content and $T_1$ with time during transpiration. Water movement in the pulvinus of Mimosa plants was visualized by Tamiva et al. by sequential images. Information on water transport can be obtained from data other than simply proton density. For example, several studies have utilized the variance in $T_1$ relaxation times to elucidate paths of transport in tissue. A sophisticated tool for measuring water diffusion in plants is available in the form of diffusion-weighted imaging. This has been applied to water and xylem flow in the plant.
stem.\(^7\)\(^-\)\(^9\) Drought-stressed plants were compared with well-hydrated plants and the distribution of water was imaged.\(^\text{100}\)

\section*{5.2.6 Roots}

MRI provides, under controlled conditions, a unique tool for studying roots in soil. Several early studies showed the feasibility of detecting roots in soil.\(^8\)\(^1\)\(^-\)\(^8\)\(^3\) Rogers and Bottomley\(^8\)\(^3\) characterized natural and artificial soils with respect to their suitability for NMR studies. Loamy sand soils are among the best for MRI, yielding a minimal background signal even with a high water content and providing an excellent medium for root MRI.\(^8\)\(^3\),\(^8\)\(^4\) Care must be taken when using either natural or artificial soils that the concentration of paramagnetic species be kept within acceptable limits. Water uptake in roots from surrounding soil has been measured in Loblolly pine seedlings.\(^8\)\(^5\),\(^8\)\(^6\) Root growth has been followed in the Loblolly pine over several months using 3-D imaging techniques\(^4\)\(^7\) (Figure 8a and b). In this way, root length, volume and growth pattern could be monitored noninvasively under physiologically relevant conditions. Changes of \(T_1\) of water in regions of nodulated soyabean roots were studied by MacFall et al.\(^8\)\(^7\) under differing perfusion (\(O_2\), air, \(N_2\)) conditions. Matyac et al.\(^8\)\(^8\) were able to image over several weeks the growth of nematode-induced galls on tomato roots in soil. Overall MRI has clearly established itself as a technique to visualize roots in situ.

\section*{5.2.7 Single-cell Imaging}

The advances in gradient and probe technology have permitted MRI resolution and sensitivity to reach the microscopic scale (resolution < 40\,\mu m), which leads to
the possibility of using MRI to visualize single cells. Since 1986, several studies of (relatively large) single cells have appeared; a few of these have reported the resolution of single plant cells. Harrison et al. and McFarland and Mortara both reported images of large single-cell algae. Imaging of higher plant cells has been accomplished for onions, although the resolution did not permit the detection of cell organelles. Further advances in methodology are needed for the wider use of MRI for microscopy of plant cells.

5.3 Nuclear Magnetic Resonance Spectroscopy of Plants

NMR spectroscopy of plants provides information on low molecular weight metabolites and ions in plant cells. The spectra of plants resemble liquid-phase spectra and are generally acquired on liquid-phase (“high-resolution”) spectrometers; solid-phase NMR of plant cell walls is not covered here. NMR of purified plant extracts is treated separately in section 5.4. NMR spectroscopy of plants has been reviewed by leaders in the field, treated here are its salient features.

In contrast to the preponderance of proton data for the MRI of plants, spectroscopy has been effectively applied to $^1$H, $^{13}$C, $^{15}$N, $^{23}$Na and $^{31}$P nuclei; problems with overlap of complex spectra over the narrow 0–10 ppm range of proton chemical shifts have helped to accentuate the importance of heteronuclear studies for plant NMR. For metabolic studies $^{31}$P and $^{13}$C are the most useful nuclei (Figures 9 and 10a–c); the low $\gamma$ and 1.1% natural abundance of the latter nucleus lead to sensitivity problems that can be alleviated by the incorporation of $^{13}$C labels, which in turn provide a fruitful avenue for tracing metabolic pathways. The $^{15}$N nucleus has even lower sensitivity than $^{13}$C and is likewise isotopically rare; enrichment for use in studying nitrogen metabolism has proven attractive. Some studies have been performed probing ion concentrations and flux using $^{23}$Na- and $^{39}$K-NMR. In contrast to MRI, where studies have been spread over a range of plant structures, spectroscopic studies have favored perfused seedlings and root tips, along with cell cultures, which can be inserted in relatively high density into a liquid NMR probe of 5–20 mm diameter with an appropriate perfusion system. An effective perfusion system is critical to NMR spectroscopy of plant systems, and in addition to providing nutrients, oxygen and ions, the perfusion medium should have a minimal concentration of whatever nucleus is under study (to minimize the background signal) and a minimal concentration of paramagnetic species (to limit the broadening of lines).

Figure 9 In vivo $^{13}$C-NMR spectrum of maize seedling root tips, perfused with nitrogen-saturated 50 mM [1-$^{13}$C]glucose–0.1 mM CaSO$_4$. The dataset was acquired in 1 h. Roots were prelabeled with oxygenated 50 mM [1-$^{13}$C]glucose for 8 h prior to data acquisition. Peak assignments: 1, $b$Glc-C1; 2, $a$Glc-C1; 3, other sugar peaks; 4, 2-aminobutyrate-C2 (external reference); 5, 2-aminobutyrate-C3; 6, lactate-C3; 7, alanine-C3; 8, 2-aminobutyrate-C4. (Reproduced from Roberts and Xia by permission of Academic Press.)

Figure 10 In vivo $^{31}$P-NMR spectra of maize seedling root tips under (a) oxygenated conditions or (b, c) anoxia. Peak assignments: 1, Glc-6-P; 2, other monophosphate esters; 3, cytoplasmic P$_i$; 4, vacuolar P$_i$; 5, $\gamma$-nucleotide triphosphates; 6, $\alpha$-nucleotide triphosphates; 7, uridinediphosphoglucose and nicotinamide adenine nucleotides. Note the increase in the width of peak 3 from spectrum (a) through spectrum (c), indicating increasing heterogeneity of cytoplasmic pH. Spectrum (c) was acquired over the same 1-h time period as the $^{13}$C-NMR spectrum in Figure 9. (Reproduced from Roberts and Xia by permission of Academic Press.)
5.3.1 pH Measurement

The capability of NMR to measure intracellular pH via the pH-dependent chemical shift of low molecular weight metabolites was both an early and yet a continuingly useful application of in vivo plant NMR. The $^{31}$P shift of inorganic phosphate has proved particularly useful owing to its ubiquity and easy detection in all plant tissues. Also used have been the pH-dependent chemical shifts of organic acids such as malate and citrate, which are especially useful for characterizing vacuolar pH.\textsuperscript{100}

5.3.2 Metabolic Studies

The use of $^{13}$C labels provides an excellent, non-invasive way of tracing metabolic pathways in plants in vivo. Chang and Roberts\textsuperscript{101–103} used $^{13}$C-NMR to study inorganic CO$_2$ fixation in maize roots. They also characterized carbonic anhydrase activity by saturation transfer $^{13}$C-NMR. Carbon metabolism, specifically in the form of malate synthesis and degradation, has been followed in maize root tips\textsuperscript{101–103} and cultured sycamore cells.\textsuperscript{104} The results show that metabolic pathways can be followed in vivo in the fashion of classical radioisotope studies with $^{14}$C, but with the advantage of real-time noninvasive monitoring. Monitoring nitrogen metabolism via $^{15}$N is another application of in vivo plant NMR spectroscopy. Examples include the study of the biosynthesis of secondary metabolites\textsuperscript{105,106} and the study of the release of ammonium from glutamate in carbon-starved carrot cells\textsuperscript{107,108} (Figure 11a–d). $^{15}$N Labels have been used to characterize the assimilation and metabolism of ammonium and nitrate.\textsuperscript{107,109} Uptake of sodium ion and its compartmentalization (intracellular vs extracellular) using shift reagents have been studied by $^{23}$Na-NMR.\textsuperscript{110–112} $^{31}$P-NMR can be used to characterize cytoplasmic vs vacuolar P$_i$.\textsuperscript{113} Inorganic phosphate metabolism has been a frequent topic of $^{31}$P-NMR studies. Lee et al.\textsuperscript{113} showed that plant cells maintain level P$_i$ concentrations under a variety of nutritional conditions, and Lee and Ratcliffe\textsuperscript{114} showed that 1 $\mu$M external P$_i$ was sufficient to maintain constant P$_i$ in maize seedlings. Measurement of rates of synthesis of ATP from P$_i$ using $^{31}$P saturation transfer in maize root tips has been carried out by Roberts et al.\textsuperscript{115,116} 

5.3.3 Physiological Response to Environmental Change

Response of plants to hypoxia (low oxygen conditions) has been an area of high interest. Response of metabolism in plant tissues to hypoxia has been successfully characterized by both $^{13}$C- and $^{31}$P-NMR.\textsuperscript{116–119} As has been pointed out by scientists and historians alike, irrigated agriculture carries the seeds of its own destruction in the deposition of salt in irrigated soil, and probing the response of plant tissues to salt stress is an active area of plant NMR. Roberts et al.\textsuperscript{115} used $^{31}$P-NMR to show enhanced P$_i$ uptake in maize root tips under high-salt conditions. Spickett et al.\textsuperscript{112,120} also used $^{31}$P-NMR of maize root tips to characterize the effects of salt stress on intracellular pH, P$_i$, and phosphorylcholine. Effects of extremes in pH, which can occur in soil or from influences such as acid rain, have been probed by both $^{13}$C- and $^{31}$P-NMR.\textsuperscript{104,121} Gout et al.\textsuperscript{104} showed that intracellular and vacuolar pH in sycamore cells are independent of external pH in the range 4.5–7.5, but outside this range become more aligned with the external pH value.

5.3.4 Combined Spectroscopy and Imaging

The combination of imaging and localized spectroscopy is an intriguing area that has been the subject of much interest in the medical field (e.g. Gillies\textsuperscript{122}). Imaging and spectroscopy can be thought of as interfacing in two
ways. The first is the use of CSI to generate images of the distribution of specific substances in plants based on their chemical shift differences. Generally in CSI a selective pulse excites the chemical shift of interest, followed by application of an imaging sequence to provide the spatial distribution of the species chosen by the selective pulse. CSI is aided by high fields, since isolation of particular metabolites in the image is dependent upon chemical shift differences. The second interface of imaging and spectroscopy is the use of the field gradients employed for imaging to achieve localized spectroscopy of a specific area; in its most elegant form, an image for morphology is obtained first, followed by spectra localized to a region of interest.

5.3.4.1 Chemical Shift Imaging of Plants Oil distribution is usually easy to image selectively owing to the prominent lipid methylene resonance, which is well separated from that of water. Examples of images of oil distribution include those for olives\(^{123}\) and coconuts.\(^{124}\) The spatial distribution of sucrose and other metabolites have been imaged in *Ricinus communis* hypocotyls using CSI at high spatial resolution.\(^{125,126}\) Sugar distribution in grapes was imaged by Pope et al.\(^{127}\) Goodman et al.\(^{128}\) used CSI to follow the distribution of sugars in ripening grapes, observing that initial sugar gradients in the immature grape changed to an even distribution throughout the mesocarp at maturity. Tse et al.\(^{129}\) have imaged the sugar distribution in pea.

5.3.4.2 Localized Spectroscopy of Plants Fewer studies of localized spectroscopy have been published, but interesting work has appeared. Jagannathan et al.\(^{124}\) used image-guided localized proton NMR to observe changes in fluids in coconut during maturation (Figure 12a–c).\(^{130}\) Localized spectroscopy and \(^{13}C\)-NMR have also been used to probe the distribution and identity of sugars in germinating barley seeds.\(^{130}\)

5.4 Nuclear Magnetic Resonance Spectroscopy of Plant Extracts

In contrast to the more recent development of MRI and in vivo spectroscopy for the study of plants, high-resolution liquid-phase spectroscopy of natural product plant extracts dates back over several decades. The literature covering the determination of plant natural product structures by NMR is vast and no attempt will be made to cover it. Here only salient features of this field will be briefly treated.

The usual purpose of the study of isolated pure plant compounds by NMR is to establish scalar and dipolar connectivities leading to the identification of molecular structures. Recent developments in 2-D NMR, inverse detection, gradient methodology and microprobes have all contributed to a major revolution in the power of NMR methods applied to plant extracts and the ease with which total structures are elucidated. We shall look briefly at each of these aspects.

5.4.1 Two-dimensional Nuclear Magnetic Resonance Methods

Early studies of plant extracts, like all NMR, were limited to 1-D studies, principally of \(^1H\) and \(^13C\). The development of COSY\(^{17,131}\) and then TOCSY\(^{132}\) 2-D scalar correlation methods enabled vicinal (\(^{1}J_{HH}\)) and geminal proton (\(^{2}J_{HH}\)) couplings to be elucidated throughout a molecular backbone (Figure 13a–c). Other 2-D pulse sequences also proved to be powerful tools for determination of molecular structure (see below).

5.4.2 Inverse Detection

It is well known that the chemical shift dispersion of $^{13}$C (200 ppm, about 20-fold that of $^1$H) provides an attractive route to well-resolved spectra, but at the cost of insensitive detection of the rare $^{13}$C spin. The development of inverse-detected 2-D methods, where correlations are established between X nuclei and $^1$H with $^1$H detection, permitted assignments of both $^{13}$C and $^1$H spectra and elucidation of $^{13}$C-$^1$H $J$-coupled partners without the need for isolating the large amounts of material routinely required for traditional $^{13}$C studies. The one-bond $^{13}$C-$^1$H correlations are obtained via HSQC or HMQC type experiments as shown for crytospirolepine (1) in Figure 13(a) and (b). Frequently in natural products, saturated carbons, carbonyls or heteroatoms disrupt proton connectivity networks and necessitate the use of NMR techniques that can “navigate through” these structural features. The HMBC (heteronuclear multiple bond correlation with $^1$H detection) experiment and more recent variants allow the determination of $^2J_{CH}$ correlations and also $^3J_{CH}$ and $^4J_{CH}$ correlations, and are invaluable techniques for assignment and structure determination in “proton-poor” natural products (Figure 14).

5.4.3 Gradient Methodology

Adding to the power of the inverse detected methods, and also other NMR techniques, has been the development of pulsed-field gradients for liquid spectroscopy. The gradients serve two primary purposes: coherence selection and solvent suppression. Gradient selection of coherence replaces, partially or entirely, methods based on phase cycling and enables some 2-D data to be collected with only a single scan per $t_1$ increment when sufficient material (with microprobes < 1 mg is sufficient) is available as no minimum phase cycle is required. When sample limitations require signal averaging, gradient methods are still preferable, especially in inverse-detected experiments, for the production of artifact-free spectra. Normally plant natural product spectra are acquired in deuterated solvents but with small sample amounts even the residual proton of a deuterated solvent can be troublesome, and gradient methods provide improved solvent suppression over traditional presaturation methods.

Figure 13 Segments of the COSY (b) and HMQC (a) spectra of cryptospirolepine (1) acquired at an $^1$H frequency of 400 MHz. Trace (b) shows $^3J_{HH}$ scalar correlations and trace (a) shows single-bond carbon–proton correlations. Peak labels correspond to the numbering of structure (1). (Reproduced from G.E. Martin, R.C. Crouch, in Two-dimensional NMR Spectroscopy, eds. W.R. Croasman, R.M.K. Carlson, VCH, New York, 873–914, 1994, © 1994 VCH Publishers, Inc. Reprinted by permission of John Wiley & Sons, Inc.)
techniques needed for molecules that do not yield to the basic experiments. Generally a COSY or TOCSY experiment provides $J_{HH}$ correlations. HSQC and HMQC yield $\chi_{CH}$ correlations and HMBC the $J_{CH}$ and $J_{CH}$ correlations. In many cases this is sufficient to determine the complete structure. Where resolution is poor HMQC–TOCSY or HSQC–TOCSY 2-D spectra provide proton correlation maps “edited” by the chemical shift dispersion of $^{13}$C. For nitrogen-containing compounds a $^{15}$N–$^1$H HMOC can be used to locate and assign the chemical shifts of nitrogens. The utility of low-level, long-range $^1$H–$^{15}$N correlations has also been reported recently. Additional, more elaborate techniques can be utilized, but those listed here are frequently sufficient to elucidate total structure, i.e. the relative configuration of all chemically bonded atoms in the molecule. Tertiary structure, used in the sense of protein NMR, is less of a concern in natural products. Where spatial (dipolar), as opposed to bonding (scalar), interactions need to be determined, then nuclear Overhauser spectroscopy (NOESY) experiments or the related rotating frame nuclear Overhauser enhancement spectroscopy (ROESY) can be performed (Figure 15). The ROESY experiment is the one of choice in many cases since for mid-sized natural products at high field the nuclear Overhauser effect (NOE) may be negligible.

5.4.4 Microprobes

Commercial manufacturers over the last few years have developed probes with 2.5–3-mm diameters with outstanding performance, typically achieving 40% more sensitivity than comparable 5-mm probes. These tubes use <150 μL of solution, and with “plugs” at either end of the sample constructed of materials matched to the magnetic susceptibility of the NMR solvent, volumes <80 μL can be utilized, with concurrent reduction of sample size to 10–100 μg. It has therefore become possible to determine total structures of natural products using amounts of material an order of magnitude less than possible just a decade ago. Recently, probe diameters and sample volumes have been further reduced with the advent of 1.7-mm “submicro” probes that utilize just 30 μL of solution. These probes produce an impressive 2.3-fold improvement in sensitivity over the 3-mm probe and further lower the minimum amount of sample needed for structural studies.

5.4.5 Total Structure Determination: the Strategy

The NMR suite of techniques utilized for structure determination will necessarily vary with the material studied, with a greater number of, and more complex, 

Figure 14 HMBC spectrum acquired in 16 h with a 250-µg sample of structure (1) in a microinverse detection probe at 11.75 T. Peak labels correspond to the numbering of structure (1). Cross peaks represent mostly $J_{CH}$ correlations along with some $J_{CH}$ correlations. (Reproduced from G.E. Martin, R.C. Crouch, in Two-dimensional NMR Spectroscopy, eds. W.R. Croasmun, R.M.K. Carlson, VCH, New York, 873–914, 1994 © 1994 VCH Publishers, Inc. Reprinted by permission of John Wiley & Sons, Inc.)

Figure 15 ROESY spectrum of structure (1). Cross peaks represent close dipolar contacts between protons. The cross relaxation between the N-Me groups and the various ring systems is shown on the figure. (Reproduced from G.E. Martin, R.C. Crouch, in Two-dimensional NMR Spectroscopy, eds. W.R. Croasmun, R.M.K. Carlson, VCH, New York, 873–914, 1994 © 1994 VCH Publishers, Inc. Reprinted by permission of John Wiley & Sons, Inc.)
while the rotating frame nuclear Overhauser effect (ROE) suffers no such limitation.\(^{(152)}\)

5.4.6 On the Horizon

The impact of 2-D methods, inverse detection, field gradients and high-sensitivity microprobes and submicromprobes for natural product analysis has been immense. Further technical advances in liquid NMR are continually appearing. The recent use of 1.7-mm diameter probes has allowed a further reduction of the sample amounts needed for analysis (see section 5.4.4) and more routine use of such probes is likely to occur in the near future. Combination LC/NMR spectrometers\(^{(153)}\) allow the separation of natural products and “on-line” NMR analysis to be conducted simultaneously and may well prove to have a great impact on plant natural product characterization. Superconducting probes offer greatly enhanced sensitivity compared with standard room-temperature probes. The use of superconducting probe technology is only just appearing in the literature\(^{(154)}\) and the high cost of these devices currently is a significant barrier to their widespread use, but the anticipated pay-off in sensitivity, thereby further lowering the minimum sample amounts required, will be a powerful driving force for their utilization. Finally, continuing the trend towards smaller probes with higher sensitivity, “microcoils” for use in liquid NMR spectroscopy have recently been fabricated.\(^{(155–157)}\) These coils have diameters considerably less than 1 mm for sample volumes far less than 1 \(\mu\)L. Although applications to date are limited, this technology has the potential yet again to reduce significantly the sample amount needed for analysis by virtue of its dramatically enhanced mass sensitivity.

Techniques are described for determining particle size in food dispersions involving food particles ranging in size from 0.1 to 1000 µm, where the presence of the particles confers special properties such as texture, appearance or flavor release. Those foods of plant origin that are cellular in nature are outside the scope of this article, as their structure is not under the control of the food manufacturer. The techniques described are used to a greater or lesser extent on foods, and they are all methods in use in other industrial sectors. The techniques are classified according to their underlying physical principle. Summary tables are provided to act as quick reference guides for a potential user of the technique. After the detailed descriptions, the final section groups those techniques relevant to a specific type of dispersion.

The two most direct methods, microscopy and sieving, are discussed initially followed by three classes of optical technique, comparatively simple forward or back scattering, angular-dependent light scattering and dynamic light scattering. The next technique to be addressed is the electrical sensing zone originally developed by Coulter. Sedimentation techniques follow: gravitational sedimentation, centrifugal sedimentation and field-flow fractionation (FFF). All depend on the behavior of the particles in a force field that is balanced by viscous drag forces. The next two techniques are both acoustic in operation, either direct ultrasonic attenuation or electroacoustics. Finally, the novel applications based on nuclear magnetic resonance (NMR) are presented.

1 INTRODUCTION: THE IMPORTANCE OF PARTICLE SIZE

It is difficult to formulate a meal without including particulate foods. The particles include gas bubbles in bread, oil droplets in dairy products and sugar crystals in chocolate. The presence of the particles gives the food its character, texture and flavor. The long-term stability is also critically affected by the type and size of the particles in the food. Table 1 gives examples of the particles occurring in a range of foods, their size range and the properties affected by the particle size.

Particles may be gas, liquid, solid or biological. Other particles such as the filled cells in plant tissue are outside the scope of this article, which is confined to systems where the particle size is controllable and an important factor in the properties of the food. The particles of interest in foods are generally in the range 0.1 µm to 1 mm because particles in this size range have the most dramatic effect on the quality of foods.

There is a scarcity of texts devoted solely to particles in foods, but much of the colloidal literature is relevant, and this article draws heavily on particle sizing techniques developed originally for the chemical or mineral industries. The best sources of information on colloidal systems are those by Dickinson and Stainsby (food), Becher (emulsions) and Allen (general particle sizing).

Figure 1 A typical log-normal size distribution of an oil-in-water emulsion measured using a variable-angle light scattering sizer. (a) Volume distribution using log(diameter) axis. (b) Volume distribution using linear diameter axis. (c) Number distribution using log(diameter) axis. (d) Number distribution using linear diameter axis.

Techniques are classified by the physical principle underlying the measurement. The emphasis is on instruments that are available commercially and are most commonly used for food materials. Special emphasis has also been given to the new techniques, such as acoustics and NMR, where there is potential for increased applications in the future. Each section is headed by a summary table for quick reference, and the last entry presents an overview of the techniques suitable for each type of application. The critical factors in selecting the
best method for a particular application include accuracy, susceptibility to perturbing factors, ease and speed of use, breadth of distribution, intrusiveness, preparation procedure (e.g. dilution), commercial availability and cost. The article attempts to address the majority of these factors; the issues of commercial availability and cost are omitted, but Allen \(^{(3)}\) gives an excellent list of the instruments currently available.

Particles in food are rarely all the same size (monodisperse), and for many purposes it is important to measure the whole distribution of sizes present. A common distribution produced by a milling or homogenization process is the log-normal distribution of diameters. Figure 1(a) shows the droplet size distribution in an emulsion, expressed as the volume in each size band, where the size bands are plotted on a logarithmic scale. This is the form of data produced by instruments with a wide particle size range, such as the variable-angle light scattering technique described in section 3.2 below. The general Gaussian shape of the distribution, when plotted against log(diameter), indicates the log-normal nature of the distributions. The volume-mean diameter, commonly denoted by \(D_{43}\), is calculated to be 2.56 \(\mu\)m, close to the major peak of the log-normal curve. The data are not exactly log-normally distributed, as a small second peak is observed at approximately 12 \(\mu\)m. However, if the same data are plotted using linear diameter bins, as in Figure 1(b), the skewed shape is evident, and the apparent bimodality disappears. The same set of particle size data can be shown as a number distribution, which is the primary output of techniques involving individual particle counting, such as the electric sensing zone method described in section 4 below. Figure 1(c) shows the previous data converted to a number distribution, where the results are expressed as the number (as a percentage of the total number) of particles in each diameter bin. Comparison with Figure 1(a) shows the dependence of the shape of the distribution on the analysis protocol. In practice it is best to express data in the form (volume or number) that is closest to the primary data collected by the instrument, as the conversion process gives emphasis to regimes of diameter that may not have been warranted by the original measurement. For example, if data are initially collected by volume, which emphasizes the larger diameter fractions, then conversion to a number distribution can give large errors in the number of small particles where the instrument measured very low volumes. Counting methods are often best when the distribution of particle sizes is not very wide; in a highly polydispersed sample, a very large number of particles needs to be detected and classified in order to accumulate enough counts in the largest size categories. The number distributions can also be expressed in linear or logarithmic size bands, and Figure 1(d) shows the effect on the shape of the distribution of plotting on a linear scale.

Even where it is convenient to use a mean value of diameter, the distribution determines the relationship between the various types of mean obtained for a sample. Table 2 shows the definitions of the most common mean values used to describe a particle size and its distribution and the calculated means for the distribution in Figure 1. The data show, for example, that the mean diameter calculated in order to obtain a total surface area of the particles (\(D_{32}\) in Table 2) is invariably smaller than that which, when cubed, gives the average particle volume (\(D_{43}\)).

It is worth remembering in the discussion of particle size that no two techniques ever agree exactly, and there is always a debate as to the value of the “true” size. In practice, the test is whether the measurement gives results that are transparent in their analysis and are proved to be useful in the design and control of foods. Polydispersity and irregular shape are two recurring features, and the optimum technique for a specific product depends on the end-use property that is important. For example, if stability to separation is important, the hydrodynamic diameter is the appropriate size parameter.

2 DIRECT TECHNIQUES

2.1 Microscopy

Microscopic techniques are summarized in Table 3.

2.1.1 Description of the Technique

Microscopy is the forerunner of all other sizing techniques. It is still seen by some as the "gold standard" as it provides reassuringly direct visual images of the particles. The traditional instrument is the light microscope, capable of imaging and photographing particles in the range 3–150 µm with accuracy, provided that optical contrast can be achieved. Larger particles may be examined using a small magnifier or with the naked eye. Particles smaller than 3 µm may be observed using visible light, but diffraction effects cause overestimation of the diameters by up to 10%. (5) Dry powders can be viewed, but most applications require the sample to be presented as a thin film of particles in an appropriate nonswelling liquid(4) sandwiched between two glass surfaces. Biological systems may need to be stained to achieve the required contrast, and bacteria are at the resolution limit of optical microscopy. Fluorescence techniques use a dye to provide emission in the ultraviolet spectrum, with improvement in resolution proportional to the wavelength. Differential interference techniques are also valuable, to improve contrast between biological cells or oil droplets and an aqueous suspending medium without staining. If the particle is nonspherical, its projected area depends on the orientation on the slide.

Most food systems scatter light strongly, and samples require dilution to resolve nonoverlapping particles. The use of laser scanning confocal microscopy has allowed optical observation of more concentrated dispersions, to a depth of several particle diameters if the particles have been made strongly contrasting using fluorescence techniques. (5) The instrument uses a pin-hole to restrict the image to light scattered from a thin plane at a chosen depth within the sample. The light scattered by the particles in other planes is eliminated by the pinhole; consequently, an image is obtained only of the particles at the required depth. Confocal microscopy has been applied to on-line imaging.

Particles approaching the resolution of optical microscopy are usually subject to visible Brownian motion and image capture must be rapid. It is important to obtain thin specimens without deforming the particles or causing fractionation when excess dispersion flows outside the field of view.

Visual observation or measurement from photographs is very time-consuming if the size distribution has significant width, and care is needed to ensure that representative particles are selected for estimation of their size. (6) As a guide, if particles are counted randomly until the largest size category has collected at least 25 particles, the volume mean will have an error of typically 2%. (3) Each particle usually requires refocusing, as the depth of field is rarely sufficient to observe the range of particles at a single working distance. In recent years, automatic image analysis techniques have enabled more rapid quantification of particle size distributions, but they

SEM, scanning electron microscopy; TEM, transmission electron microscopy.
still depend on the preparation technique, the choice of particles to analyze, depth of focus, the contrast that defines the edge of the particle and shape effects.

Image analysis is the preferred method of characterizing food foams. Solid foams, as in bread and cake, are straightforward to prepare, as a cut edge enables both cell sizes and the cell wall thickness to be measured. Liquid foams are more difficult to handle and are often very unstable. One protocol involves preparing the foam by sparging gas through a known volume of surfactant solution in a glass-walled container. Images of the bubble size viewed through the wall are captured photographically or with a video recorder, and processed using image analysis software. On-line versions of the technique have been developed to monitor in real-time the foam structures produced in processes such as ice-cream manufacture.

Electron microscopy is used to examine and measure the size of particles below the optical range. Scanning electron microscopy requires the sample to be mounted with the particles projecting from the surface, usually achieved by freeze-fracturing procedures, and coating with a conducting layer to present a surface of uniform reflectivity for the electron beam. The scattering intensity as a function of angle is then simply related to the relief of the surface. Particles in the range 0.02–1000 µm are readily examined and measured using this technique; however, since the samples are prepared by fracturing the particles, the estimation of size requires correction factors to account for nondiametric fracture planes. For spherical particles, there are simple algorithms to convert the apparent diameters to the overall size distribution. Scanning electron microscopy is routinely used to examine biological particles such as bacteria, which are marginally too small for optical methods. It is also used for characterizing the small bubbles and particles in complex food dispersions such as ice cream. Very small particles may be viewed using transmission electron microscopy, which has a resolution of less than a nanometer. Samples are prepared by replication, which requires the particles to be initially projecting from their substrate. It is rarely used for analysis of food particles.

2.1.2 Advantages and Limitations

There is an argument that every sizing experiment should start with examination of the sample in a microscope, to determine the state of dispersion. Microscopy remains one of the fundamental characterization techniques. However, it is highly intrusive, usually requiring dilution or elaborate preparation protocols, and is time-consuming as a primary method for quantitative particle size analysis.

There is always a risk that the preparation or examination procedure changes the particle size or shape, whether by dissolving, flattening, overheating or damage by an electron beam. Since comparatively few particles are viewed in any one slide, the sampling procedure needs to be rigorous. Foams present special problems, as the viewed surface may not be representative of the bulk. Microscopic techniques are superior to other methods for characterizing the shape of particles, provided that the particles are randomly oriented with respect to the viewing direction. Images of irregular particles can be analyzed to give fractal dimensionality from measures of the projected perimeter lengths and particle area.

2.2 Sieving

Techniques to assess particles by sieving are summarized in Table 4.

2.2.1 Description of the Technique

Sieving is one of the oldest particle classification methods; it is very heavily used to characterize flours and starches.
The principle is that a particle will pass through the holes in a sieve if two of the dimensions are both smaller than the mesh size. The majority of milling and dry-grinding operations in the food industry rely on sieving to grade the particles and determine their size distribution. The fractions may be separated for different purposes, or the data used to control the milling conditions. Sieves are available in a wide range of mesh sizes, from macroscopic dimensions down to about 5 μm. The apertures are usually square, prepared by weaving wires or synthetic fibers, or circular drill-holes. Banks of sieves are used, the coarsest at the top, with successive mesh sizes reducing by $\sqrt{2}$ in mesh diameter. The sample is loaded onto the top sieve and vibrated until typically 98% of the powder has passed through at least the first mesh. For very small particles, less than 20 μm, wet sieving is used, where the particles are dispersed in a liquid and forced by pressure through the apertures. Ultrasonic waves are used as aids in wet sieving to generate standing waves that suspend the particles according to their volume, which fractionates the suspension prior to the sieving (filtration) process.\(^{(3)}\)

2.2.2 Advantages and Limitations

The use of sieves is very simple and appealing as a direct method. Sieves allow powders and wet particles to be classified as well as sized, and the technique is universally recognized, with associated industry standards. However, the method is very time-consuming and does not give precise size distributions. Fine sieves clog very easily, and the cleaning process can cause damage to the delicate materials. If the particles are irregular in shape, they may get caught on different sieves depending on the agitation and their orientation on the mesh. Many food powders, such as flour, sugar and starches, are very sensitive to humidity in the atmosphere, and the sieving process is hampered by particle aggregates. Violent agitation to disrupt the aggregates can also damage the sieve mesh.

A number of factors have been found to affect the results of sieving operations.\(^{(3)}\) These include the duration of sieving, the variation of sieve apertures from the quoted size, wear, errors of sampling and the effects of different equipment and operation. The use of small volumes in each operation provides more rapid separation but may lead to inaccuracies in recovering and weighing small amounts. In wet sieving, the particles have to be dried before weighing, which introduces a further error in handling.

When a particle can only pass through the sieve if it is presented to the mesh in a particular orientation, it is termed a “near-mesh” particle. The fate of such a particle varies according to the probability of its approach in a certain orientation, and its shape. There are mathematical procedures to estimate the shape of particles using well-defined square mesh sieves.\(^{(13)}\)

3 OPTICAL METHODS

3.1 Light Transmission and Back-scattering

Table 5 summarizes the characteristics of light transmission and back-scattering methods.

3.1.1 Turbidity

One of the simplest measurements to make, although not to analyze, is the turbidity of a suspension or emulsion. The sample is placed in a thin glass optical cell and inserted into the path of a laser beam or other monochromatic light source. The intensity, $I$, of the transmitted beam is measured using a photodetector and compared with the intensity $I_0$ of the transmitted light when the cell contains the continuous phase alone. The turbidity $\tau$ of the dispersion is defined by the Beer–Lambert law (Equation 1):

$$I = I_0 \exp(-\tau L)$$

where $L$ is the path length of the light in the sample (cell width). The turbidity depends on the concentration of the particles and their scattering cross-section, which in turn is related to the particle cross-sectional area.\(^{(14)}\) In principle, if the concentration, refractive index contrast and absorbance of the particles are known, the mean particle area can be derived from a single turbidity measurement, but in practice, several wavelengths of light are used and calibration data obtained for the dispersion under investigation. If the particles are very well characterized in terms of their optical properties, the use of several wavelengths and Mie theory enables the distribution of particle diameters to be inferred.\(^{(15)}\)

The technique is routinely used to determine the droplet size of raw and homogenized milk, and after the acidification step in cheese-making. It is also used to determine the emulsifying index of emulsifiers, where the total droplet area is the property required.\(^{(16)}\)

3.1.2 Optical Sensing Zone

The optical sensing zone technique\(^{(17)}\) is similar to the electrical sensing method in section 4 below. Particles are detected as they obscure a beam of light. Their passage produces a change of transmitted light intensity that is related, via the refractive index contrast, to the size of the particle. Calibration is required on the same type of particle because of the refractive index dependence. It is suitable for particles between 0.5 and 1000 μm in diameter.

A dynamic version of the optical sensing zone technique has been developed to monitor aggregation in water treatment processes or mineral processing.\(^{(18)}\) In this
The fluctuations of light intensity resulting from particles passing through a beam are recorded, and the ratio of the root-mean-square value to the time-averaged mean gives the number and scattering cross-section of the particles. It is generally used to observe changes in particle size and number caused by aggregation but could, in principle, be calibrated to give absolute values.

### 3.1.3 Related Techniques Using Back-scattered Light

A variant of the optical sensing zone measures the light scattered back from a particle as it flows through a focused laser interrogation zone. The use of a very fine beam and reflected light means that individual particles are sampled even in moderately concentrated dispersions (a small percentage volume per volume). The individual particles produce pulses in light intensity the size of which is related to the diameter of a chord of the particle, so number and chord length are separately recorded. Provided that the shape of the particle is known, the number distribution of diameters may be obtained for a range of 1.0–1000 µm. Although not common in the food industry, there are on-line versions available that are in use for suspensions of irregular solids, such as silica, and for flocs or aggregates.

Another related technique has been developed recently to characterize the bubble size distribution in liquid foams. The foam is prepared under controlled conditions within a tall column. A fiber optic probe (20 µm diameter) is inserted into the foam and moved up or down at a constant speed, typically 10 cm s⁻¹. The fiber and associated detectors and circuitry detect the reflection coefficient of a beam of light projected ahead of the moving fiber tip. The instantaneous value of the reflected beam is dependent on whether the fiber tip is in the middle of an internal film or within a gas bubble in the foam. Sampling the reflected signal at a rate of 1 MHz provides a data point every 0.1 µm in the foam, to obtain a detailed distribution of chord lengths from bubbles in the interior of the foam. Analysis of the chord lengths assuming spherical bubbles gives a bubble size distribution covering the range 50 µm to several millimeters. The technique does not need calibration as it measures directly the distance across each bubble it encounters, but the data can be checked by comparing the measured gas/liquid ratio with the overall density of the foam.

### 3.1.4 Related Technique: Flow Cytometry

The use of flow cytometry to obtain particle size employs a forward light-scattering technique. It is used principally on biological dispersions, and bacteria are the main food-based application. Individual particles (cells) are enclosed in a sheathing fluid and passed singly through an optical illumination and detector system. The intensity of forward-scattered light from the laser beam that impinges on the cell is related directly to its cross-sectional area. For rod-like bacteria, the flow cytometer can provide an
estimate of both characteristic dimensions of the cell. By detecting the fluorescence of the cell at a range of wavelengths, the flow cytometer can also distinguish cells of different species, either naturally fluorescent or after staining. The use of viable stains distinguishes live and dead cells, and the detector signals can be used to control electrodes to divert the particle stream into different collection pots according to size or viability.

3.1.5 Advantages and Limitations

The majority of the light transmission or reflection methods are nonintrusive and rapid to use, with comparatively simple apparatus, comprising a light source and detector electronics. Measurements are made only in the forward or backward direction; consequently, the light source and detector system may be mounted permanently in a fixed position. The samples need to be very dilute for turbidity or forward scattering using the optical sensing zone method. Dispersions of higher concentrations may be characterized by back-scattering (reflection), but as the methods require interrogation of single particles or single aggregates there is still a practical concentration limit of typically 5% (v/v). The single-particle methods may need to accumulate data over a timescale of at least minutes. Although ideal for comparative measurements, the data are complex to analyze from first principles, and calibration is usually needed to obtain absolute particle size data.

The dynamic versions are particularly well suited to monitoring processes in-line and are in common use in environmental applications. More complex devices include flow cytometry, designed to characterize multiple features of biological particles. Flow cytometry is unsurpassed in its ability to distinguish different populations of cells, by size or by their uptake of a specific fluorescent stain. However, it is inconvenient and slow for routine use on nonbiological particles.

The technique to characterize bubble size in foams has some particular features. This method measures directly the internal chord lengths of each foam bubble sampled, but it is limited by the diameter of the fiber optic probe (currently 20 µm). The probe is intrusive, which may affect the stability of the foam, and the tip may become coated with liquid which perturbs the data from the gas phase. However, it has been shown to give total gas volumes that agree well with the overall density of the foam. The technique is suitable for food and beverage foams of varying stability, which are very difficult to characterize by other techniques.

3.2 Variable-angle Light Scattering

Characteristics of variable-angle light-scattering techniques are summarized in Table 6.

3.2.1 Description of the Technique

Variable-angle light-scattering techniques measure the angular distribution of light scattered by particles in air or liquid. Both the intensity and the angular distribution of scattered light depend on the particle size. For large particles (approximately 10 µm or more), Fraunhofer diffraction theory is applicable, which treats each particle as a black disc that diffracts a laser light beam in a characteristic angular pattern, the first maximum being at an angle $\theta = \lambda / d = 3\pi / 2$ where $\lambda$ is the wavelength of the light and $d$ the disc diameter. Clearly, a polydisperse size distribution will have a set of superposed diffraction patterns, corresponding to each population. Smaller

</table>
particles require a much more detailed theory of light scattering, developed by Gustave Mie. The full treatment requires the refractive index of both media, and the particle absorbance. In principle, the angular distribution of light is only dependent on those factors, and the particle size, so the technique may be considered absolute. The commercial instruments combine the material constants into a single parameter, the presentation value, from which the scattering pattern for a specific distribution of particle sizes can be predicted. Comparison of the predicted pattern with the measured intensity as a function of angle provides a basis for iteration of the predictions to obtain the best estimate of the size distribution.

The commercial instruments may be used to size solid, liquid or biological particles. Some models have a facility for spraying a powder or an aerosol into the light path, but most sample chambers are designed for liquids. The cells contain a stirred dispersion of the particles, at low concentration to avoid multiple scattering effects. An axially mounted photodiode monitors the intensity of the unscattered beam to ensure that the turbidity (obscuration) remains in the range 5–40%. For particles of 1 µm, this corresponds to approximately 0.004–0.01% (v/v). The optimum concentration varies with particle size and the presentation value; for example, particles of 100 µm are measured in the range 0.1–1% (v/v). The overall obscuration value also serves as a test on the scattering model used to analyze the data. The scattered light is analyzed as a function of angle using a special lens system (Fourier transform lens) that collects the scattered light from all the particles illuminated by the beam (up to 20 mm diameter) to get a stationary scattering pattern on a set of semicircular detectors. The number of detectors determines the resolution in measured scattering angle; modern instruments typically have 256 detector channels. Figure 2 shows the principle of operation of a commercial sizer.

3.2.2 Advantages and Limitations

The advantage of variable-angle laser light scattering to measure particle size is its applicability to a very wide range of materials and size ranges. Most instruments have lenses of different focal lengths, enabling them to assess solid or liquid particles in the range 1 µm to 1 mm. Obtaining accurate data for particle sizes < 1 µm is more complex, as the light is scattered to very wide angles, which are difficult to obtain practically. Although some information can be gained from the scattering pattern at lower angle, fitting the shape of the rising edge of the primary peak, it is not reliable for real, polydisperse systems with a significant fraction of small particles. Some modern instruments utilize an additional feature to characterize particles in the range 0.1–1 µm. The technique is based on the difference in scattering from vertically and horizontally polarized beams of light, which is dependent on frequency and particle size. This improves the resolution of small particles and extends the range of the diffraction-based instruments.

The methods are suitable for highly polydisperse systems with each lens system capable of spanning typically three decades of particle diameters. Since a volume distribution is obtained, the larger particles tend to dominate and it is unwise to convert the data to number or area distributions when there is a high level of polydispersity. The method relies on established optical models, but the analysis procedure involves many steps, and experimental uncertainty in the measured data can result in erroneous predictions of the particle size distribution. It is also not always straightforward to obtain the parameters for the predictions (the presentation value), as the refractive index and absorbance of the particles may not be known or may vary within the sample. It is also possible that the presence of surfactant or other adsorbed species on the surfaces of particles may perturb the optical properties. In practice, it may be necessary

![Figure 2 Principle of the variable-angle light-scattering particle sizer. (Reproduced by kind permission of Malvern Instruments Ltd. © Malvern Instruments 1999.)](image-url)
to conduct preliminary experiments to determine the appropriate presentation value. These may be calibration runs with particles of known size, or a protocol where the obscuration values and fitted size distributions are examined for consistency with varying concentrations of the same sample.

The technique is applicable to dry powders, provided that appropriate sample-handling systems are used: powders dispersed in a nonswelling liquid, oil-in-water or water-in-oil emulsions, bubbles in liquid (provided they are comparatively stable) and biological systems such as yeast and bacteria. The samples must be stable to dilution; as a result, this may not be the system of choice for slightly soluble particles or reversible aggregates. The sample cells can usually be sterilized if necessary, and there are adaptations of the instruments to sample from a process line to obtain real-time particle monitoring.

Recently, there have been modifications to the technique to enable measurements to be made on concentrated colloidal dispersions, such as undiluted milk and parenteral emulsions. The instrument is based on the same principles as the commercial sizers, but the samples are enclosed in a flat cell the thickness of which is variable between 10 µm and 5 mm. The use of very thin samples reduces the likelihood of multiple scattering. The technique also works at higher turbidity, up to 70%, by incorporating the effects of multiple scattering in the algorithm that converts the scattering data into the particle size distribution. Another extension of the technique, currently under development, is to characterize the fractal dimensionality of aggregates of polydisperse particles.

### 3.3 Dynamic Light Scattering

Particle analysis by dynamic light scattering is summarized in Table 7.

#### 3.3.1 Description of the Technique

Dynamic light-scattering techniques are based on the Stokes–Einstein relation between the unhindered diffusion coefficient $D$ of a colloidal particle in a liquid and its diameter $d$ (Equation 2):

$$D = \frac{kT}{3\pi\eta d}$$

where $k$ is the Boltzmann constant, $T$ the absolute temperature and $\eta$ the shear viscosity of the suspending phase. For particles < 1 µm, the diffusion is rapid enough to be readily measurable, and the diffusion coefficient provides a measure of the particle diameter. A number of particle-sizing instruments are based on this principle, using photon correlation spectroscopy to measure $D$. The principle is illustrated in Figure 3.

Figure 3 Principle of operation of dynamic light scattering to measure particle size. (Reproduced by kind permission of Malvern Instruments Ltd. © Malvern Instruments 1999.)
from the light scattered by single particles or molecules in a colloidal dispersion or polymer solution. Static light scattering averages the scattered light, often as a function of angle or wavelength, and obtains particle information from the overall intensity of light. In dynamic light scattering, the fluctuations (speckle pattern) in the scattered beam at a given angle provide information on the rate of particle movement owing to diffusion. There are several ways of looking at the phenomenon. One approach is to consider the fluctuations to reflect the instantaneous position of particles in the illuminated volume. As the particles move within the volume element, their position causes changes in the optical path length and, thus, in the phase of scattered light. The changes in phase are directly related to the distance moved during the sampling time. The time between successive changes in phase is a consequence of a characteristic diffusion time for the particle, then the two values will be correlated, i.e. both will be high or both will be low. The sum of the product of the two values of intensity for the total measurement time \( t \) provides the autocorrelation function \( g(\tau) \) (Equation 3):

\[
g(\tau) = \langle I(t) \times I(t + \tau) \rangle
\]  

(3)

The autocorrelation function is related to the diffusion coefficient of the particles by Equation (4):

\[
g(\tau) = A + B \exp(-\Gamma \tau)
\]  

(4)

where \( A \) and \( B \) are instrument factors \((B > A)\) and \( \Gamma \) is the decay rate, linearly related to the translational diffusion coefficient \( D \).

Therefore, the diffusion coefficient is derived from the decay rate \( \Gamma \) of the autocorrelation function. If the particles are monodisperse, the analysis shows a linear dependence of \( g(\tau) \) on \( \tau \). Polydispersity is detected by curvature in the log correlation function versus correlation time. Then a set of exponential functions must be fitted to the autocorrelation function \( g(\tau) \) versus \( \tau \).

3.3.2 Advantages and Limitations

Dynamic light scattering is currently the accepted technique for small particles and polymer molecules, which are difficult to characterize by other methods. The precision is high for the estimation of the mean size and polydispersity index of narrow distributions and the measurements are comparatively rapid. However, longer correlation times are needed if there is considerable polydispersity, as the fitting of multiple exponential functions to a single measured curve requires a large number of data points. In wide distributions, another major problem is that the scattering intensity rises with \( d^6 \); consequently, large particles dominate over small ones.

Many instruments measure at a single angle – usually 90° to the incident light beam – but improved measurement time and resolution can be gained by measuring at a range of angles. The optimum range, even if the intensities owing to different particles are equalized, is when the largest particles are no more than twice the diameter of the smallest ones. However the resolution can be improved by combining the dynamic measurements with angle-dependent static light scattering.

4 ELECTRIC SENSING ZONE

Table 8 summarizes the features of the electric sensing zone technique.

4.1 Description of Technique

The electric sensing zone technique is based on the difference in dielectric properties of particles and a surrounding liquid (Figure 4). It was originally developed for blood cells but is now used for a variety of solid and liquid dispersions. The particles are suspended in an electrolytic solution and passed through a small aperture. Electrodes on either side of the aperture measure the change in impedance as the particle passes through the gap. The change in impedance is directly related to the volume of electrolyte displaced by the particle, and since each particle passes individually through the aperture, each one is counted. The number of counts recorded for each size of pulse (divided into up to 256 analysis bins) gives the number distribution of particle volume. This is readily converted into the equivalent spherical diameters, volume distributions, etc. as required.

The range of the instrument is dependent on the aperture size. A commercial instrument, the Coulter Multisizer, uses apertures from 15 to 2000 µm. Particles can be sized if they fall in the range 2–60% of the aperture diameter; therefore, in principle, the instrument has a total range of 0.3–1200 µm. Calibration is required for each aperture to obtain the geometric and electrical constants that convert the pulse height into the required particle volume. Polystyrene latex size standards are used to obtain the calibration values. Provided that the sample particles are also nonconducting and spherical, the calibration is valid for any type of (nonporous) particle.

4.2 Advantages and Limitations

The method has the attraction of counting individual particles, with minimal calibration. It is suitable for a wide range of particle type, including biological systems such as blood cells and bacteria. It is excellent for particles in a comparatively narrow size range, accessible by a single aperture size. Where there is a high level of polydispersity, a full size distribution may be built up from measurements made using several apertures, but it is not always straightforward to link the individual distributions into a single data set.

Errors may occur as a result of more than one particle passing through the aperture at any one time (coincidence), but the modern instruments detect this by recording an anomalous pulse shape and discarding the data point. The dilution of the suspension should be adjusted to reduce coincidence to less than 10% of the total count. High dilution means an increase in measurement time, as typically counts are made of approximately 30,000 particles, but this is rarely a limitation in practice, with most characterizations completed within 10 s. An anomalous pulse shape also occurs for spherical particles that pass off-center through the aperture, and these data are also automatically discarded. The volume of nonspherical particles may be measured, but there is an error associated with the irregular pulse shape caused by the orientation of the particles in the aperture, and it may preclude the detection of coincident particles, thus broadening artificially the size distribution. Clearly, the measured diameters relate to the sphere of equivalent volume.

The instrument requires dispersal of the particles in an electrolyte, usually an aqueous salt solution, and this may change the size or stability of certain samples. The electrolyte must be very clean if the small apertures are used because these are prone to blocking by small aggregates of particles or contaminants. The sample must also be robust to a high level of dilution; therefore, the particles must be highly insoluble in the liquid. The technique is not suitable for porous particles or gas bubbles.
5 SEDIMENTATION

5.1 Gravitation

Gravitational sedimentation techniques are summarized in Table 9.

5.1.1 Description of the Technique

Gravitational sedimentation techniques for particle sizing are based on the application of Stokes’ law to the individual particles in a (dilute) settling or creaming dispersion. If the particles are denser than the surrounding liquid, they have a tendency to sediment; less dense and the process is called creaming. The term creaming derives from the behavior of oil-in-water emulsions such as milk. The basis of Stokes’ law is that particles of different density to the surrounding fluid move under gravity and against a fluid resistance until a constant, terminal velocity is attained. The gravitational force is related to the volume of the particle, and the resistance is determined by its surface area and velocity. When the two forces are equal and opposite the particle is moving at a constant (terminal) velocity, \(V_s\), given by Equation (5):

\[
V_s = \frac{\Delta \rho g d^2}{18 \eta}
\]  

where \(\Delta \rho\) is the difference in density between the particle and liquid, \(g\) is the acceleration from gravity, \(d\) is the particle diameter and \(\eta\) the viscosity of the continuous phase.

The practical issue is to measure the terminal velocity of the particles. This is normally done by assaying a dispersion for particle concentration, where changes with time are analyzed in terms of particle flux and, therefore, velocity. A large number of instruments are available to obtain this information.\(^{(3)}\) The simplest are intrusive, where a pipette (e.g. the Andreason pipette) is used to sample a dispersion as a function of time, and sometimes vertical position, to conduct off-line concentration assays on the portion removed. A hydrometer may be suspended in a dispersion to monitor the density of the dispersion with time, from which the particle concentration may be inferred. Other devices employ a scale pan suspended in the dispersion to weigh the particles landing on it. Analysis of the signal from an optical concentration scanner is complex (see section 3.1 above) as the turbidity, usually measured at a single frequency, is a function of the concentration and particle size distribution of the particles in the beam; however, this analysis is suitable for very low concentrations. For concentrated dispersions, the concentration–height information may be collected using X-ray attenuation,\(^{(30)}\) capacitance measurements\(^{(31)}\) or ultrasonic density profiling.\(^{(32)}\) In the last (Figure 5), the time-of-flight of a pulse of ultrasound is measured as it passes through the sample. This value is converted to speed of ultrasound, which is usually a simple function of dispersion concentration. Measurement at a series of heights allows detailed characterization of the sedimentation or creaming process, as shown schematically in Figure 5. The concentration profiles are converted into particle velocities and then diameters, using Equation (5).

5.1.2 Advantages and Limitations

The use of gravitational sedimentation techniques is confined to particles that have a Stokes’ velocity that is significantly larger than their movement owing to diffusion. In practice, this restricts the use of the techniques to particles of the order of 1 \(\mu\)m and larger, up to a maximum determined by the need to maintain

laminar flow (Reynolds number < 0.25), which typically gives an upper limit in the region of 200 µm (depending on density difference and viscosity). The dispersion concentration should be low, <0.2% typically, to ensure that the particles are subject to individual movement unperturbed by each other. However, there are correction factors for dispersions of higher concentration that allow for backflow and the hindrance caused by particle interactions.\(^3\)[33,34] The X-ray, capacitance and ultrasonic techniques are particularly suited for the sedimentation of concentrated dispersions, which is important where the particle size may be affected by dilution or where the aim is to characterize weak aggregates. The values of particle size obtained from sedimentation techniques are always based on hydrodynamic diameters, requiring complex analysis if the particles are not uniform in composition and shape, as in the case for porous particles or floes.

The simplicity of many of the sedimentation techniques makes them an attractive and cheap option for particle sizing in liquid dispersions. They are commonly used for powders dispersed in nonswelling liquids, and the ultrasonic method has been applied to food emulsions. In many cases, the distribution of hydrodynamic diameters is the property required, in order to predict or control separation under gravity, but care must be taken in comparing the data with other measures of diameter, particularly for irregularly shaped particles or aggregates.

### 5.2 Centrifugation

Centrifugal sedimentation is summarized in Table 10.

#### 5.2.1 Description of the Technique

The principles in centrifugal particle sizing are identical to those in gravitational methods. The particles are made to move in a centrifugal field, which fractionates them according to their hydrodynamic diameter. The samples are enclosed in a disc that is spun; the concentration of particles passing a fixed diameter on the disc is monitored. The detection device is usually an optical photocell, and analysis is complicated by the factors described in section 3.1, the turbidity of the dispersion being a complex function of particle concentration and size distribution. Measuring the particle concentration using X-rays is also available in a commercial instrument,\(^3\)[30] which provides

</tbody>
</table>
unambiguous concentration data at the selected position on the disc.

5.2.2 Advantages and Limitations

The disc centrifuge technique is well established in the food industry, being in routine use for characterizing emulsions. It is suitable for much smaller particles than gravitational sedimentation techniques, and for larger particles it is the more rapid technique. It provides a full hydrodynamic size distribution, and the complexities of analyzing the concentration using optical scattering are avoided in the X-ray versions of the instrument. For small emulsion droplets, however, if there is a substantial amount of emulsifier on their surfaces, the overall density of the particles may not be well known, and in some cases a thick protein layer can make oil droplets denser than a surrounding aqueous phase. If the particles deform under the centrifugal forces, inaccurate results may be obtained. The dispersion must be stable to dilution, to ensure individual particle movement according to Stokes’ law.

5.3 Field-flow Fractionation

The technique using FFF to analyze particle size is summarized in Table 11.

5.3.1 Description of the Technique

FFF is a variation on the sedimentation techniques. The method uses a gravitational or centrifugal field to fractionate the particles into size zones, which are washed out (eluted) in turn by a fresh fluid. Solid or liquid particles may be characterized, and the method provides hydrodynamic diameters of nonspherical particles.

Centrifugal fields are most commonly used to determine the size of particles in the range 0.005–1 µm. Essentially the apparatus consists of a flattened toroid tube containing the sample. Input and exit channels allow filling and emptying. The sample cell is set spinning with the continuous phase of the dispersion, to set up a centrifugal field across the chamber. The sample [containing particles at less than 0.2% (v/v)] is injected into the field and the particles separate into regions of varying size. The centrifugal forces are balanced by the back diffusion of the particles against the concentration gradient generated by the centrifugal field. Large particles are flung to the outside of the tube, and smaller ones remain suspended. The field is controlled to achieve maximum separation of the particles in the sample. When the particles have reached their equilibrium positions in the field, a fresh sample of continuous phase is passed through the tube. Using laminar flow conditions to obtain a parabolic velocity profile, the particles at the center of the tube are collected first, followed by the larger size fractions. The concentration with elution time is monitored using optical detectors to obtain the concentration of material that was suspended at each position in the tube. This information allows a full size distribution to be accumulated, usually over a timescale of up to an hour.

5.3.2 Advantages and Limitations

The wide range of FFF instruments available cover a correspondingly wide size range. Within any one sample, the conditions can be set to fractionate to the required resolution, or to emphasize certain parts of the size distribution. Controlling the spin speed to slow down exponentially during the collection process allows the particles to emerge according to a log-linear relationship between mass and retention time. The process can be controlled to be gentle if required, to characterize aggregates or unstable particles.

</table>
The analysis of the turbidity/time data to obtain the particle size distribution is multistaged, involving knowledge of the optical properties of the dispersions (and their variation with particle size), the flow profile of the eluting fluid, the centrifugal field at each point in the tube under the conditions chosen, and the sedimentation properties of the particles in the dispersing liquid. The fractionation system is never perfect, and a monodisperse sample will still result in a distribution of elution times. This zone broadening generates apparent polydispersity in the derived size distribution. Recent developments are overcoming this problem by using refined detection procedures, involving multiangle light scattering to quantify the polydispersity of each fraction during elution. In this mode, the FFF instrument is operating primarily as a fractionator to prepare near-monodisperse samples for the light-scattering analysis to give the size distribution of each fraction. The advantage over merely using the light-scattering instrument is the resolution obtainable when analyzing sequential samples of limited polydispersity.

6 ACOUSTIC TECHNIQUES

6.1 Ultrasonic Spectroscopy

The principles of ultrasonic spectroscopy for analysis of particle size are described in Table 12.

6.1.1 Description of the Technique

Ultrasonic spectroscopy is based on the size-specific interaction between high-frequency sound (ultrasound) and colloidal particles in suspension. In some ways the technique is analogous to the scattering of light by small particles; it is distinct in that ultrasound is a longitudinal wave and not subject to polarization, and most applications of the technique involve particles smaller than the wavelength of the ultrasound. There are a number of different mechanisms that contribute to the scattering or absorption of ultrasound by particles, which is altered by the contrast in the physical and thermal properties of the particles and the surrounding liquid. Since the contrast in these properties between a liquid and a gas bubble is very high, a small amount of entrained air in a dispersion renders it effectively opaque to ultrasonic characterization.

Ultrasonic sizing measurements are usually made in the straight-through direction using a pair of transducers facing each other across the dispersion. The frequency of the ultrasound is varied, and the overall attenuation of the signal by the dispersion is measured. The attenuation of most dispersions increases strongly with frequency, usually as (frequency)^2, so measurements at high frequency are made using a reduced path length. Either a pulse of ultrasound is used to irradiate the sample with a wide range of frequencies in a single measurement, which are analyzed separately, or the frequency is changed for each determination. In both cases, a spectrum of ultrasonic attenuation as a function of frequency is obtained, which is inverted to obtain an inferred particle size distribution. Commercial instruments operate in the frequency range 1–200 MHz and can characterize particles between 0.01 and 1000 μm. Unlike light, it is possible to propagate ultrasound through concentrated dispersions, and particle volume concentrations up to 50% are accessible, although the analysis is considerably simplified if single scattering can be assumed, which requires concentrations of a small percentage (volume per volume).

6.1.2 Advantages and Limitations

The advantage of ultrasonic attenuation for particle sizing is its ability to characterize concentrated dispersions. The

</tr>
</tbody>
</table>
ultrasonic waves propagate readily through dispersions of up to 50% (v/v), although it is not straightforward to remove the effects of multiple scattering from the analysis of the particle size. With an appropriate choice of frequency, ultrasonic instruments are applicable to solid or liquid particles in a very wide range of diameters.

In recent years, several commercial ultrasonic particle sizers have become available. Some have a requirement for a large volume of sample (several liters), which may be inconvenient for certain applications. The other major limitation to the current applications lies in the difficulty of using the complex ultrasonic scattering theory to invert data to yield a polydisperse size distribution. Even for monodispersions, full implementation of the scattering theory requires 14 parameters (particle and liquid density, ultrasonic attenuation and velocity, viscosity or modulus, thermal expansivity, specific heat capacity and thermal conductivity), many of which are not known to a high degree of precision. For mineral dispersions (e.g. silica in water), the physical properties dominate and the thermal ones are less important. For these systems, the inversion of the ultrasonic spectra to obtain particle size distribution is relatively straightforward. However, all the parameters contribute for emulsions, and the results obtained are sensitive to the values of the parameters that are assumed. Although, in principle, the technique is absolute, involving independently derived parameters, in practice it is usually necessary to conduct calibration experiments with the dispersions of interest to obtain data sets for comparison with the spectra of unknown samples. There is a detailed protocol required for robust fitting of the ultrasonic attenuation spectra to particle size distribution and concentration.

The ultrasonic technique is suitable for installation in a processing line, to give real-time changes in particle size. The ultrasonic properties are sensitive to aggregation and currently the theories are being extended to characterize the degree of flocculation, floc size and structure using ultrasonic spectroscopy. There is no doubt that ultrasonic techniques will be developed further and become routine for a number of particle sizing applications. The application to biological systems is problematic, as they are typically of low volume concentration and there is little physical contrast between the cells and the suspending liquid.

6.2 Electroacoustics

Electroacoustic techniques are summarized in Table 13.

6.2.1 Description of the Technique

The use of electroacoustics involves a complex series of measurements. First, an electric field is applied to a sample in a cell, pulsed at a frequency in the megahertz range. A piezoelectric transducer at one end of the cell detects the ultrasonic wave generated by the action of the pulsating electric field on the (charged) particles in suspension. The amplitude of the acoustic waves is related to the electrophoretic mobility of the particles, which in turn is related to their charge and hydrodynamic properties in the suspending liquid. The second step is the determination of the acoustic impedance of the dispersions by measuring the reflection coefficient of an ultrasonic wave propagated from the transducer into the suspension. The theory assumes a constant charge density on the surfaces of the particles and fits a monomodal size distribution (e.g. log-normal) to the electrophoretic mobility spectrum collected at a range of applied frequencies. Calibration experiments are conducted to characterize the electrical constants in the instrument and to provide a background value to allow

</tbody>
</table>
for the effect of the ions in the suspending liquid. The technique is routinely used to determine the zeta potential (charge density) of particles, such as the protein-coated emulsion droplets in milk.\(^{(47)}\) Various manufacturers of instruments claim they can cover different ranges of particle size, from casein micelles\(^{(47)}\) of the order of 0.01 µm, to silica suspensions containing particles 10 µm in diameter.\(^{(46)}\) The frequency range depends on the size required and the density difference between the particles and the suspending liquid; values quoted are from 0.3 to 100 MHz.

The electroacoustic theory was originally proposed for noninteracting particles, which restricted the application to low concentrations of a small percentage volume per volume, but recently extensions have been developed to model the electroacoustic properties of dispersions up to 50% (v/v).\(^{(48)}\) An on-line application is also reported. The method is not restricted to aqueous dispersions, and it has been used to monitor the size of the water droplets in food water-in-oil emulsions such as spreads.\(^{(49)}\)

### 6.2.2 Advantages and Limitations

The technique of electroacoustics is still in its infancy, and the coming years are likely to yield new developments and modifications to extend the applications of the method. It has the advantage of being nonintrusive and capable of characterizing many dispersions without dilution. In principle, it will have value in characterizing reversible aggregates, although their theoretical analysis will be challenging. The technique is most accurate when applied to particles of narrow size distribution, with a well-defined charge density and in dilute concentrations [\(<5\%\text{ (v/v)}\)]. The application of the theory to concentrated dispersions up to 60% (v/v) is currently restricted to particles that have a density close to that of the suspending liquid.\(^{(48)}\)

In 1996, the use of combined acoustic attenuation spectroscopy and electroacoustic measurements has been reported.\(^{(50)}\) This combination helps to overcome the problems of fitting electroacoustic theory to concentrated dispersions and offers potential for the increased use of acoustic techniques in colloid particle sizing.

### 7 NUCLEAR MAGNETIC RESONANCE

NMR can also be used to analyse particle size (Table 14).

#### 7.1 Description of the Technique

The sample is subjected to a pulsed magnetic field at radiofrequencies. The magnitude of the field varies with position in the sample, creating a gradient. At a characteristic frequency and field strength, the nuclei in the molecules resonate and cause a small net loss in the energy of the magnetic pulse, detected by measuring the strength of an echo in the absence and presence of the molecules of interest. The position of the molecules in the magnetic field gradient affects the amplitude of the echo, and diffusion of the molecules during the echo

time causes a detectable phase shift of the echoed pulse. As a result, the distribution of diffusion rates of the molecules may be measured as a distribution of echo magnitudes and phases. If the molecules are constrained within a spherical cavity such as a droplet, those near the walls of the cavity suffer restricted diffusion compared with those in the center of the cavity. The size of the cavity determines the proportion of molecules within it that are subjected to restricted diffusion over the timescale of the experiment. The droplet size is estimated from the proportion of molecules exhibiting restricted diffusion.\textsuperscript{(51)}

7.2 Advantages and Limitations

NMR apparatus is highly complex and comparatively expensive, although now benchtop instruments are available. The main advantage of the technique for droplet sizing is its ability to characterize the molecules of interest (those inside the droplets) in the presence of other components, in a liquid or a solid continuous phase and in very concentrated dispersions.\textsuperscript{(52)} The method has been used to examine food emulsions, particularly water-in-oil systems such as spreads,\textsuperscript{(53)} which are difficult to characterize by other methods. Similarly, since the diffusion of water inside biological cells is restricted by the cell wall, in principle NMR methods can be used to determine the size of bacteria and yeast.

The analysis of the NMR results in terms of particle size distribution requires the application of several models: those associated with the response of the nuclei to the field, the effect of diffusion in the gradient, the assumption of spherical geometry and extraction of effective droplet area from the diffusion data, and the fitting of a simple size distribution. It would be difficult to use the methods for a very skewed or multimodal distribution of sizes or to apply them to droplets that might vary in composition. The methods can be used for droplet sizes in the range 0.1–10\(\mu\)m, which is convenient for many food emulsions unless severe coalescence has occurred. However, to access the full range of sizes, a number of different experimental conditions must be used, which hinders the speed of measurement and may make it less useful for rapidly changing sizes. The technique provides information on the primary droplet size and is not sensitive to flocculation. However, in principle, if the molecules of the continuous phase are subjected to restricted diffusion because the droplets increase the tortuosity of the liquid channels between them, examination of the diffusion rates of the molecules in the external phase may provide microstructural information. The technique has also been applied to examine the voids in a solid foam.\textsuperscript{(54)} and is one of the few methods to be applicable to nonintrusive evaluation of the microstructure of cheese.\textsuperscript{(55)}

7.3 Magnetic Resonance Imaging

In magnetic resonance imaging, the internal structure of a food is probed nonintrusively to provide a chemical map.\textsuperscript{(56)} In principle, any spatial change in composition resulting in contrast in the NMR signal may be processed to form an image of the cross-section under examination. The resolution of current imaging techniques is of the order of 10\(\mu\)m; consequently, the technique has considerable potential for measuring food particles, including foam bubbles.\textsuperscript{(57)}

8 EVALUATION OF THE AVAILABLE TECHNIQUES FOR DIFFERING PARTICLE TYPES

8.1 Powders

It is important to know the particle size of powders to optimize processing operations such as baking, to control the bulk density when powders are packed or in storage hoppers and to prevent dust in the atmosphere. In foods requiring control of the size of solids in the finished product (e.g. sugar crystal size in chocolate), it is convenient to monitor the size before combining with other ingredients. Powders are generally in the larger size range of food particles, over 10\(\mu\)m, and they are amenable to size analysis using microscopy, sieving, variable-angle light scattering and the optical obscuration technique. Of these methods, the most highly automated is the variable-angle optical method, and the size range is accessible using comparatively simple diffraction theory. A number of commercial sizers have dry powder feeders to present the sample to the measuring system. Clearly, if there is a suitable carrier liquid, the full range of liquid sizers can be used.

If the powder is of irregular shape, and this is of interest, there is little alternative to the use of microscopy and image analysis. Modern software offers a range of options for characterizing the shape parameters of irregular solids.\textsuperscript{(12)}

8.2 Emulsions and Suspensions

Food emulsions and suspensions contain a very wide range of particle sizes, and the optimum instrument depends heavily on the specific sizes required. For comparatively narrow distributions, containing particles above 0.3\(\mu\)m that are robust to immersion in electrolyte, there is no substitute for the electric sensing zone methods, providing direct counting of particles classified by volume. If the distribution is broader, then the variable-angle light-scattering techniques are useful; it is claimed that the commercial instruments have a
lower limit of 0.05 µm. However, the small particle fractions are difficult to characterize accurately in a broad distribution. Similarly, the centrifugal and FFF techniques are capable of characterizing broad size distributions, in the 0.1–10 µm range.

The techniques listed so far have all required the use of very dilute samples. If the dispersion is changed by dilution, the particles can be characterized using: confocal or electron microscopy; gravitational sedimentation using X-ray, capacitance or ultrasonic detection; ultrasonic attenuation; electroacoustics, or NMR techniques. NMR is particularly useful where the continuous phase is nonaqueous and/or solid, as in water-in-oil spreads. Development in the area of acoustic attenuation may provide an alternative in the future.

A comparison of different techniques to characterize suspensions with a fairly narrow range of sizes (the largest being typically three times the smallest) concludes that there is good agreement between electron microscopy, variable-angle light scattering and dynamic light scattering, provided that the dynamic method uses an appropriate correction for polydispersity. Both light-scattering techniques were shown to be very sensitive to small amounts of aggregation. Comparison between variable-angle and dynamic light scattering of food emulsions of high polydispersity showed good agreement in the 0.1–0.6 µm range, but, as expected, the dynamic method detected a smaller fraction of droplets < 0.1 µm in diameter. To improve the resolution of dynamic light scattering, the use of nonlinear channel time was proposed. For small particles, the combined technique using dynamic light scattering to analyze samples after separation by FFF is recommended.

8.3 Foams

Foams are very difficult to characterize reliably. If the matrix is solid, as in bread or cake, microscopy and image analysis offer the best means of determining distributions of bubble size and wall thickness. In the case of liquid foams, microscopy through the wall of a container is frequently used, but there is always a concern that the bubbles at the wall may not be representative of the bulk structure. Although intrusive, the fiber optic method described above is an interesting development and may be used routinely in the future. Many researchers on food foams rely on indirect methods (for example overall volume) to characterize foam stability, instead of measuring bubble size directly. In the future, NMR techniques may be developed further in this area.

8.4 Biological Systems

Microscopy is routinely used to measure the size of individual bacteria and yeast, generally electron microscopy to obtain good resolution. The electric sensing zone method was developed initially for blood cells and has a loyal following among biologists. However, increasingly researchers are adapting optical techniques to obtain rapid measures of cell size and viability. Variable-angle light scattering has been compared with transmission electron microscopy and found to be very suitable for spore suspensions. Flow cytometry is now routine as a sensitive multipurpose technique to measure cell size and viability.

The main food application of biological particle sizing is that of yeast flocculation after fermentation processes. A number of techniques are suitable for this application, including the dynamic light obscuration method and detecting back-scattered light on-line during industrial processing.

8.5 Complex Dispersions

The term complex dispersions is used here to describe systems containing particles of irregular shape, aggregates or mixtures of different composition. If such a system is suspected, it should be confirmed by a preliminary microscopic examination if possible, before any attempt at quantitative analysis.

Nonspherical particles present problems in their detailed characterization. The only reliable method is optical microscopy, provided that the particles are larger than approximately 1 µm, robust to dilution and randomly oriented on the slide. Electron microscopy may be used for smaller particles; however, if the sample is prepared by freeze-fracturing, the correction factors for nondiometric viewing planes become very complex. Similarly, sieving provides information on the upper bound of the two smaller dimensions of a particle, and there are ways to estimate particle shape using square-mesh sieves.

All the indirect methods will provide some estimate of size for nonspherical particles, usually based on a sphere of equivalent volume, area or hydrodynamic diameter, but the usefulness of the results will depend on the aspect ratio, regularity, surface roughness, etc.

Aggregated particles also present problems, either as an unwanted perturbation in the determination of primary particle size or as the population of interest. A sizing determination resulting in a bimodal size distribution should always be investigated for particle aggregation. Optical techniques are particularly sensitive to a small amount of aggregation; to determine only primary particle size, it is important to ensure that the particles are well dispersed before proceeding with a measurement. If aggregates are present during sizing using the electric sensing zone method, they will appear as a large fraction in the measured distribution or simply block the aperture. The best method to characterize the
aggregates themselves depend on their robustness. The technique based on dynamic light obscuration\(^{18}\) was developed principally to detect and characterize strong aggregates, such as yeast at the end of a fermentation process, but in many other cases the aggregates are disrupted by dilution. These systems need techniques where higher concentrations can be used, such as sedimentation using capacitance, X-ray or ultrasonic detection, or the emerging applications of ultrasonic and electroacoustic spectroscopy. Optical methods are restricted to the back-scattered techniques developed for on-line use. NMR methods are insensitive to aggregation, in general, as the primary size will still emerge from the analysis of restricted diffusion within the droplets. However, if the aggregates are nonmobile and larger than approximately 10\(\mu\)m, magnetic resonance imaging has potential for characterizing their structure.

Microscopy and image analysis may also be used to obtain the individual size distributions of each component in a mixture, the precision depending on the ease of identification and the number of particles of each type that are analyzed. Mixed dispersions are not readily sized using optical techniques, as the optical properties are dependent on particle composition. Similarly, sedimentation methods are problematic because, even if each population of particles is characterized by a distinct range of Stokes’ velocity, the technique used to determine concentration (optical, capacitance, X-ray or ultrasound) depends on the particle properties and may not be able to provide data that can be analyzed using the appropriate parameters for each subpopulation. The overall size distribution can be measured using the electric sensing zone technique, provided that identification of the particles is not required and they are nonporous, nonconducting and within a fairly narrow size range so they are all detectable using a single aperture. The NMR techniques can measure droplet size in an emulsion/suspension mixture, as the signals from the molecules in the droplets are collected independently of other components.

ACKNOWLEDGMENTS

The author thanks David Higgs of Malvern Instruments and James Beattie of Colloidal Dynamics for information regarding their instruments. She is also indebted to colleagues at the Institute of Food Research, especially David Hibberd, Peter Wilde and Brian Hills for providing assistance in specialist techniques. The UK Biotechnology and Biological Sciences Research Council supports the Institute’s research on colloidal foods.

1 INTRODUCTION

Since the discovery of the insecticidal properties of DDT (1,1,1-trichloro-2,2-bis(p-chlorophenyl)ethane) in 1939 by P. Muller more and more molecules have been studied, synthesized and widely used to protect crops from pests. In the 1960s an american biologist, R. Carson highlighted in her book "The Silent Spring" the dangers to human health and environment related to the use of pesticides.\(^1\) The highly persistent organochlorine (OC) pesticides were found to accumulate in the fatty tissues of humans and animals, therefore in the 1970s they were banned in USA and Europe. Many alternative molecules (more selective and labile) were studied and produced so that thousands of pesticides are now in use and available. Some of these OC compounds continue however to be used in other countries for pest control in sanitary use with a rise in the kind of problems\(^2,3\) experienced in USA and Europe in the past.

On the other hand avoidance of all pesticide use may not always lead to a high quality agricultural product, e.g. “wormed” olives may have a noticeable content of oxidized oil with the undesirable products of lipid peroxidation and molds growing on stored cereals or other commodities produce toxins that could survive both food processing or an animal’s metabolic activity and could be present in everyday food like beer, milk, coffee.

1.1 Sampling

In the analysis of pesticide residues and mycotoxins, the heterogeneous residue distribution among several single vegetables or fruit composing a given lot may be due, e.g. to the fact that some are more exposed and some are less exposed during spraying in the field of pesticides, or for mycotoxins, to variations in conditions affecting mold growth in different parts of the stored commodity. Usually the size of a sample collected for...
pesticide analysis is of the order of a few kilograms of vegetables. Obviously this problem may be of less importance for those commodities that are already in a homogeneous form (e.g. wine, juices, milk). The Codex Alimentarius\(^{(14)}\) gives detailed guidelines for sampling: the number of primary samples must be related to the size of the lot and the minimum sample sizes recommended vary from 2 kg for large vegetables, to 1 kg for vegetables and to 0.5 kg (generally) for fatty products. In particular a minimum of 3 (for lots \(> 50\) kg) to 15 primary samples (for lots over \(2000\) kg) and between 6 and 30 primary samples for lots suspected of having history of contamination is recommended.

For mycotoxins other problems arise from the very low levels of the residues investigated\(^{(15)}\) and from the very heterogeneous distribution. The variations between pesticide residues is that a single piece in a lot may be strongly contaminated with values up to a tenth of a microgram per gram, caused by molds developed there. For these reasons correct sampling must encompass large amounts of each commodity in order to have at least one contaminated piece and a representative sample from the lot; furthermore each sample must be well homogenized to achieve representative subsamples for laboratory analysis. Literature reports sample sizes of 5–30 kg for the analysis of mycotoxins in different size lots.\(^{(6,7)}\)

A review of suitable methods for correct sampling in food analysis was published by Horwitz.\(^{(8)}\) Studies\(^{(9)}\) also point out the increase in the error when decreasing the amount of sample collected.

**2 PESTICIDES**

**2.1 Problem of Pesticide Residues in Food**

All pesticides to a greater or lesser extent are toxic molecules, some exhibiting very high toxic activities for humans as well as for insects, therefore after they have performed their function and protected the plant against pests, they should have as little residue as possible. For the reasons mentioned in the introduction, several monitoring programs were started and are still fully active in countries worldwide as a technical tool for assessing residue levels. Apart from these, countries have also implemented policies to enable the best compromise to be found between protection of crops (of particular relevance in developing countries) and protection of the environment and human health from pollution by harmful substances.

Many studies and analytical methods for pesticide residues analysis are present in the literature, but the main problem for chemists working in this area is how to determine reliable data from hundreds of molecules\(^{(10)}\) that exhibit completely different properties and behaviors. The residues are in fact present at trace levels (from 0.001 to nearly 10 mg kg\(^{-1}\)) in matrices that make analysis particularly difficult with the need for complex preparative procedures and sophisticated instrumental analysis used in conjunction with different selective detectors.

Some general reviews have been published\(^{(11–14)}\) concerning methods for determining residues in plants and vegetables. Other references in this field are manuals like the FDA (Food and Drug Administration, USA) Pesticide Analytical Manual,\(^{(15)}\) the Analytical Methods for Residues of Pesticides in Foodstuffs,\(^{(16)}\) and other manuals\(^{(17–22)}\) or series of books such as those by Zweigg\(^{(23)}\) and Sherma and Cairns\(^{(24,25)}\) Detailed reviews,\(^{(26–30)}\) covering only limited topics, have been published.

**2.2 Sample Homogenization**

Sample homogenization is the first preparative step: all the vegetables composing each single sample must be homogenized by a mechanical blender. In this operation all those parts that cannot be homogenized (e.g. core of the fruits) or are of minimal relevance to the presence of residues (e.g. nonedible parts) are normally excluded. Pesticide manuals also give details of this aspect of sample preparation. Care must be taken when isolating a portion for dithiocarbamates analysis (by cutting away some pieces for a representative subsample) before homogenization since some dithiocarbamates can degrade in the mechanical milling process. About 0.5–1 kg of homogenized sample is enough\(^{(31)}\) to ensure representative data.

**2.3 Multiresidue Methods**

A considerable problem in pesticide residues analysis is that the analyst is engaged to investigate the ‘potential’ presence of several hundreds of active molecules in each commodity. To do this, the analyst needs methods that can simultaneously detect and quantify the largest number of active molecules possible. This goal is, in theory, very difficult (if not impossible) to achieve but methods are available in pesticide analytical manuals and elsewhere in the literature that can determine up to 100–200 or more pesticides at the same time. These are the so-called multiresidue methods where the preparative steps are the same for all the molecules and the instrumental determination is made on different types of instrument; usually most molecules are determined by gas chromatography (GC) with appropriate detectors and a minimum number of pesticides determined by liquid
chromatography. Methods describing the development of single multiresidue instrumental detection by GC/mass spectrometry (MS) systems have been published.\(^{60}\)

Two volumes of the FDA Pesticide Analytical Manual\(^{15}\) are dedicated to multiresidue methods; a review of official multiresidue methods was published by Motohashi et al.\(^{14}\)

Multiresidue methods cannot analyze all the active molecules at the same time; some classes (e.g. phenoxy acid herbicides, basic benimidazole fungicides or urea herbicides) require their own methods. Some advances have been reported in efforts to include part of these classes in a general multiresidue method using specially tailored sample processing or new extraction techniques.\(^{32,33}\)

### 2.3.1 Sample Preparation

Sample preparation normally consists of an extraction step and a cleanup step; several different techniques may be combined together to provide a much larger number of methods as can be seen from the abundant literature in this field. The first main division can be approximately drawn between the methods for nonfatty and fatty foods. Some authors\(^{15,34}\) classified matrices into groups that can undergo the same extraction technique, e.g. high/low water content, high/low fat content, high/low sugar content, dry commodities, high/low acidity fruits. Acetone or a similar water-soluble solvent is suggested for high-water content samples whereas dichloromethane is suggested for fatty matrices.

#### 2.3.1.1 Techniques for Extraction

The homogenized sample is normally extracted by contact with an organic solvent. In this step, because many pesticides are also present in the inner tissues of the vegetable (e.g. systemic compounds) the inner contact between the solvent and the sample is important for a quantitative extraction.

For aqueous matrices or vegetables with high-water content, solvents like acetone, acetonitrile and methanol are widely used, alone or in mixtures. Extraction is often aided by ultrasound or mechanical stirring with blenders or high-speed laboratory homogenizers to enable the solvent to penetrate the vegetable tissues deeply. Addition of a small quantity of diatomaceous earth helps the successive filtration. The extract obtained contains water and needs to be purified. In some methods, some water must be added to dry matrices like cereals before the solvent extraction.

The aqueous–organic extract then is extracted by partition with a nonmiscible solvent like the petroleum ethers, dichloromethane or chloroform or is diluted with water for cleanup by reverse phase solid-phase extraction (SPE). Aqueous samples like wine and juices are also extracted and purified directly onto reverse phase SPE C\(_{18}\) (octadecyl) cartridges.\(^{35–38}\) SPE limits the use of solvents and can also be automated, but exhibit difficulties in recovering most polar compounds; these latter, however, can be better recovered using high-surface area C\(_{18}\) SPE substrates.\(^{39}\)

Association of Official Analytical Chemists (AOAC) methods\(^{15}\) use acetonitrile for the extraction with some variants in relation to the sugar content of the matrix. Honey is usually extracted by water dissolution and direct extraction both with LLP (liquid–liquid partition) using e.g. dichloromethane,\(^{40}\) and hexane/isopropanol,\(^{41}\) and with SPE onto C\(_{18}\) functionalized silica\(^{42}\) columns.

For fatty matrices many methods\(^{15}\) extract the fat and the residue values are given in milligrams per kilogram of fat; several variations may exist with respect to all types of fatty commodities, milk, meat, fish, eggs, cheese, and so on. Commodity with low fat content (less than 10\%) may also be processed with methods for nonfatty matrices. AOAC\(^{15}\) give a method for fatty matrices extracting fat and residues by partition in petroleum ether–acetonitrile–water.

Another technique of extraction was developed\(^{43}\) using solid-phase matrix dispersion (SPMD) onto a solid phase (Florisil\(^{\circledast}\), diatomaceous earth, sodium sulfate) which provides some elimination of the water and a large exchange interface for extraction with a water nonsoluble solvent. The solvents with the best extracting power are chloroform, dichloromethane, dichloromethane–acetone 9 : 1 and ethyl acetate, the former also being characterized by low boiling temperatures for the successive concentration step. Recently similar methods were developed with less harmful solvents\(^{44,45}\) such as ethyl acetate, but with some problems due to its higher boiling point.

Some classes of pesticides, because of their acid or base properties require appropriate methods of extraction. Among these the most important are benimidazolic fungicides, phenolic and urea herbicides.

Basic benimidazole (carbendazim, thiophanate methyl, benomyl and thiabendazole) compounds are extracted by partition with an acidified aqueous or aqueous/methanol phase and an organic phase (normally ethyl acetate or dichloromethane); in a second step the acid aqueous phase is alkalinated by means of sodium hydroxide and reextracted with ethyl acetate or dichloromethane. This extract can undergo some further cleanup.\(^{15}\) Some extraction methods\(^{46}\) operate with ethyl acetate or dichloromethane in the presence of a basic medium (or other catalysts, e.g. copper acetate) which catalyzes transformation of benomyl and thiophanate methyl into carbendazim, before the acid/base partition. A study\(^{47}\) of extraction of benimidazole compound with hot pressurized water has been published.
Acid herbicides (chlorophenoxy acids and chlorophenols) are extracted in methanol acidified with sulfuric acid and with successive partition with methylene chloride, petroleum ether or other suitable solvents.\textsuperscript{15}

Urea herbicides\textsuperscript{15} are extracted with methanol whereas \textit{N}-methylcarbamates\textsuperscript{15} are extracted with methanol and partitioned with acetonitrile, then in both cases partitioning is with petroleum ether (removal of nonpolar coextractives) and dichloromethane. In some multiresidue methods it has been shown\textsuperscript{43} that urea compounds and \textit{N}-methylcarbamates are also extracted.

Developments in some methods allow harmful solvents like acetonitrile or methanol and dichloromethane to be substituted with acetone and ethyl acetate, respectively.

In a single more sophisticated experiment some new methods achieve the extraction of phenolic and the urea compounds together with the other molecules normally detected by classical multiresidue methods\textsuperscript{32} by modifying the pH value during the extraction.

Supercritical fluid extraction (SFE) is a new technique\textsuperscript{48} that operates by extracting a sample with liquid supercritical carbon dioxide instead of using a solvent. This technique, however, requires sophisticated apparatus and, at present, is not yet widely used in laboratories.

General reviews of applications of SFE in extracting contaminants from food\textsuperscript{49} or environmental samples\textsuperscript{50} are available, together with some studies for the optimization of the experimental conditions for extraction of pesticides.\textsuperscript{51,52} SFE can be performed either statically or dynamically (with carbon dioxide flowing through the sample), with several parameters having an influence on the recoveries. The operating pressure of the carbon dioxide must be above a given critical pressure where the analyte tends to increase its solubility in the supercritical extractant until it reaches a maximum, and the temperature must be optimized because an increase in temperature may or may not enhance the solubility of the analyte. These two parameters depend upon the properties of the molecules investigated. Often a modifier is added to a supercritical fluid in order to increase the polarity of the medium and achieve the extraction of polar pesticides. The water content of the sample also affects the extraction. In fatty matrices good selectivity for pesticides with respect to fat may be obtained by selecting appropriate conditions of temperature and pressure of the supercritical fluid; too high a pressure would start extraction of substances from the matrix as well and lead to a too complex chromatogram. Conditions for extracting pesticides are, for instance, pressures ranging from \(5000–10000\ psi (35–70\ MPa)\) and temperatures between \(40–80\ ^\circ\text{C}\). A limitation of SFE apparatus is the relatively small sample extraction chamber (10–15 mL) which does not allow extraction of more than 5 g of sample dispersed in a solid phase. Another step needing control in SFE is the final trapping of the analytes onto a sorbent substrate and the consequent elution with a solvent. Lehotay and Valverde Garcia\textsuperscript{53} studied a series of trap–solvent combinations, after extraction from fruits and vegetables carried out dynamically at \(50\ ^\circ\text{C}\) and \(350\ bar\); the best combination found was an octadecyl–silica trap with acetone as eluting solvent.

Accelerated solvent extraction (ASE)\textsuperscript{45,54} extracts with solvent at high pressure and temperature leading to recoveries mostly falling in the 70–110\% range with standard deviations between 5 and 11\% It represents an alternative to Soxhlet apparatus.

### 2.3.1.2 Techniques for Cleanup of the Extract

A review\textsuperscript{55} of cleanup methods was published by Tekel and Hatrik, however similar information is often included in other reviews.

Many extraction procedures already operate as a first clean up as the analytes are preferentially extracted more than many other substances contained in the matrix (matrix coextractive). This could be the case for traditional LLP or the more recent reversed phase octadecyl silica SPE and SPMD that were discussed earlier.

A traditional technique widely used to clean up the extracts is preparative chromatography onto silica, alumina, Florisil\textsuperscript{56}, or Celite\textsuperscript{57} columns which are devoted to retaining coextracted substances from the matrix. Analytes are usually eluted from the column with pure solvents or solvent mixtures effecting a compromise between elution of a wide range of compounds, recovering the most polar active molecules and limited coelution of the interferents from the matrix. Solvents normally used in mixtures are hexane, dichloromethane, petroleum ether, or acetonitrile. Florisil\textsuperscript{58} is used most and is particularly good in retaining fats; dedicated columns are needed for special cases, e.g. silver added to alumina to detect sulfur compounds present in cabbage and celery.

These cleanup procedures were developed using 6–3 mL/1–0.5-g mini columns which like those used for SPE are readily available for commercial use. Some studies have been published concerning stability of adsorbed compounds on SPE columns.\textsuperscript{57}

SPE columns are also used with other stationary phases: graphitized carbon black as a completely nonpolar substrate and the polar aminopropyl column. DeKok\textsuperscript{59} and others\textsuperscript{57} used amino columns for cleaning up carbamates prior to HPLC (high-performance liquid chromatography) analysis; for amino columns polar solvents such as acetonitrile or methanol–dichloromethane are necessary for eluting polar molecules, such as captan, acephate and vanidionith. Bicchi et al.\textsuperscript{58} and Di Muccio et al.\textsuperscript{59} achieved cleanup of acetonitrile or methanolic
extracts on Extrelut® prepacked columns and eluting with dichloromethane. Other methods were also reported using SPE columns in succession with different sorbent phases.

A method developed for fatty matrices combines a first cleanup by centrifuging at \(-10^\circ\text{C}\) in the extraction step and a successive cleanup on Florisil® cartridges.

Among the instrumental techniques for purifying the samples are gel permeation chromatography (GPC) and sweep codistillation (SCOD).

In GPC separation of the analytes onto a styrene–divinylbenzene cross-linked packed column is achieved on the basis of molecular size. Eluents used are normally dichloromethane–cyclohexane 1:1 and cyclohexane–ethyl acetate 1:1; fatty matrices are purified well with a 85:15 cyclohexane–dichloromethane solvent mixture. GPC does not always provide a satisfactory purification with respect to the costs of instrument and solvents; while fatty matrices, especially those with fat content approaching to 80–100%, are purified satisfactorily, in vegetable extracts chlorophyll is not completely eliminated. Columns are normally about 30 cm long with 2-cm diameter but some methods use a smaller diameter (1 cm) columns for a minor solvent consumption.

SCOD is a completely different technique based upon the relatively high volatility of pesticides with respect to matrix components. The sample is put into a heating device filled with silanized glass wool where an inert gas is flowing through, the analytes are distilled and transported towards a cold trap where they condense and can be recovered for successive instrumental detection.

### 2.3.1.3 Concentration of Sample Extract

The sample extracted (usually 100–200 mL) must be concentrated either for cleanup procedures or for instrumental analysis. Usually, the final purified extract is concentrated to a few milliliters to obtain 10 g of extracted vegetable in 1 mL with a ten-fold concentration factor. This concentration factor is much less than in water analysis where up to 1000-fold concentrations are usually achieved, although in the case of foods the limiting factors of concentration are coextracted substances from the matrix. It must also be considered that the injection of too concentrated extracts shortens the life of the chromatographic columns.

In the Rotavapor®, the extract is rotated in a flask at temperatures between 30–50 °C under reduced pressure, and the solvent is distilled. Extract must be only reduced to a small volume and the solvent evaporation must be completed under a gentle stream of nitrogen in order to avoid losses of the more volatile pesticides (e.g. dichlorvos, methamidophos, biphenyl, diphenylamine, dimethylaniline metabolites, acephate).

In the Kuderna–Danish apparatus the solvent evaporated from the extract by heating flows first through an expansion chamber and then through a Snyder column where the heavier fraction (which may include most volatile pesticides) condenses back; the solvent may be recovered by condensation into an apposite vessel. Some Kuderna–Danish apparatus devices achieve solvent evaporation by inert gas (nitrogen) flowing instead of heating.

### 2.3.1.4 Solid-phase Microextraction

Solid-phase microextraction (SPME) is based upon direct adsorption of the analytes from aqueous solutions onto the organic phase (polidimethylsiloxane, carbowax, divinylbenzene, methacrylate are used) coating a glass fiber. The adsorbed analytes are then directly desorbed in the injector of a gas chromatograph or in the loop (by means of a special device) valve of a HPLC.

This technique is particularly interesting because it avoids the use of solvent, simplifies the preparative step and good results were obtained in analyzing pollutant in water, as reviewed by Eisert and Levsen. This advantage is partially counterbalanced by the fact that each gas chromatographic run needs its extraction step and the calibration requires extraction for each point (in this case the concept of “recovery” is meaningless).

The first experimental applications of SPME to pesticide residue analysis on food concerned mainly wine and juices, and vegetables. The technique seems applicable for the determination of many active molecules. Honey is a particularly interesting watersoluble matrix for such an application but the high content of sugar present interferes by dirtying the fiber and causing consequent losses in sensitivity.

### 2.3.2 Instrumental Determination

#### 2.3.2.1 Gas Chromatographic Techniques

GC is the main technique devoted to the pesticide residue analysis due to its high power of resolution of complex mixtures and its high sensitivity.

Splitless or cold on-column injection are the two most used injection techniques in this analysis because pesticide residues are present in the sample at trace levels. Splitless injection preserves the clean column but introduces the sample directly into a high temperature chamber whereas cold on-column injection is undoubtedly preferred in the case of labile compounds (e.g. N-methylcarbamates), although introducing the whole extract into the column leads to a shortening of the life of the column.

There is no requirement for a specific column for analyzing pesticide residues; usually general purpose columns with nonpolar or slightly medium polar stationary phases...
are used (100% methylsilicone, or methylsilicone containing 5–50% phenylsilicone or 6–14% cyanopropylphenylsilicone). Carbowax columns are limited because they cannot reach temperatures above 220°C without bleeding, while several pesticides and several matrix substances elute at higher temperatures. Special columns also exist devoted to optimizing the separation for determinate classes of compounds (e.g. triazine herbicides).

Despite the fact that many different compounds with different vapor pressures, boiling points and polarity properties have to be analyzed and then separated, programmed oven temperature runs from 50–100°C to 250–280°C are usually used. Solvent focusing allows good separation of many compounds with temperature programs increasing from 40–50°C up to 150°C at 10–20°C min⁻¹ then slowly at 250–280°C at 2–6°C min⁻¹ (data are indicative); a further increase in oven temperature cleans the column from the heavier coextractives (e.g. chlorophyll, fats).

Detection must be both selective and sensitive. Flame ionization detector (FID) is rarely used. Electron capture detectors (ECDs) provide good detection (down to near 0.01 µg mL⁻¹ of sample extract) for OC residues and many other molecules. Herbicides and fungicides that possess halogen atoms on the molecules or have high electron affinity centers like double bonds, aromatic rings, carbonyl or nitro groups can be detected by ECD with a limit of detection (LOD) from 0.05–1 µg mL⁻¹ of sample extract depending upon the molecule. Pyrethroid insecticides and elemental sulfur are detectable at the ECD. Nitrogen phosphorus detectors (NPDs) assure good detection for all the organophosphates pesticides (LOD = 0.01–0.05 µg mL⁻¹ of sample extract) and organonitrogen herbicides like triazines. Carbamate insecticides and herbicides are detectable at the NPD only at higher concentrations (0.5–1 µg mL⁻¹ of sample extract). Flame photometric detector (FPD), although less sensitive than NPD gives good selectivities for organophosphorous and organosulfur compounds; sulfur compounds may interfere when used in the phosphorus mode.

Some molecules do not possess a heteroatom and so are not detectable by the detectors previously described. Thus the analysis must be done by a FID without any selectivity or directly by a more sophisticated system coupling a gas chromatograph with a mass spectrometer (GC/MS) used as detector. For this purpose quadrupole mass spectrometers are more suitable since they scan spectra faster where many spectra have to be scanned in the short time corresponding to the elution of a gas chromatographic peak. If the whole mass spectrum is acquired, GC/MS gives a positive identification of the compound investigated but does not allow any great sensitivity (0.1–1 µg mL⁻¹ of sample extract). In order to achieve the necessary sensitivity and selectivity, three or four characteristic mass fragments must be selected from the spectrum of the substances and the acquisition of such ions must be programmed in a time window across the retention time of the substance. Since the complete investigation may require at least two or three chromatographic runs on different instruments with different detectors, some methods were proposed that detected up to 100 pesticides in one or two GC/MS runs by programmed acquisition(60) of given fragments in given time intervals. In Table 1 are listed relative retention times with respect to internal standard fenchlorphos recorded using different columns for most common pesticides and their main mass fragments.

Some molecules require derivatization into more volatile (and/or more detectable) molecules prior to being analyzed by GC. This is the case for phenoxy acid herbicides that are converted by methylation into the corresponding methyl esters. Some other derivatizing agents act by inserting some organohalogen groups into the molecule so that it becomes detectable by the highly sensitive ECD. Methyl iodide, trifluoroacetic acid (TFA) and bistrimethylsilyltrifluoroacetamide are common derivatizing agents.

**2.3.2.2 High-performance Liquid Chromatography Techniques (Labile Molecules and High-molecular-weight Molecules)**

HPLC is used less compared with GC, but it is a necessary tool for all those molecules that are either very labile at high temperature or require temperatures too high to be eluted from the column. Compounds that are usually determined by HPLC are N-methylcarbamates insecticides, benzimidazole fungicides, urea compounds and carbamates herbicides.

Injection in the column (10–50 µL) is generally effected from a loop valve. Separations are carried out by reversed phase chromatography onto C₁₈ or C₅ bonded silica columns with acetonitrile, methanol and water as eluents with gradient elution. In order to compensate for changes in light absorption from the eluent during gradient elution and to avoid any baseline drifting, water can be replaced by dilute ammonium acetate(72) (about 0.1 mmol L⁻¹) solutions.

Fixed wavelength ultraviolet (UV) simple detection must be done by choosing an appropriate wavelength where the analyte absorption is maximized and the absorption of interfering substances is minimized. This is quite difficult in some cases because the UV spectra of some pesticides do not exhibit a characteristic peak of absorption. Diode array detectors (DADs), which acquire the UV spectrum in real time, provide special aid in identifying the eluted compound by the UV spectrum pattern. This is of noticeable importance for those molecules that cannot be analyzed at all by

a Data from ARPA Dip. di Torino using 30 columns (0.25-mm internal diameter and 0.25-μm film thickness) and the following temperature program: 1 min at 100°C, from 100°C to 190°C at 7°C min⁻¹, 5 min at 190°C, from 190°C to 250°C at 5°C min⁻¹, 10 min at 250°C, then from 250°C to 270°C at 5°C min⁻¹.b Data from PMIP – ASL Como using a 30 column (PTE-5 and OV-1) 0.25 and 0.32-mm internal diameter, 0.25 and 0.4-μm film thickness, respectively and the following temperature program: 1 min at 60°C, from 60°C to 150°C at 25°C min⁻¹ and to 270°C at 5°C min⁻¹; 15 min at 270°C.c (xx) = good detectability; (x) = medium to scarce detectability. d Use also ions with m/z = 178 and 187 in the case of the presence and coinclusion of chlorpyrifos methyl.

GC/MS (at least for qualitative confirmation) and when the laboratory does not possess MS interfaced HPLC. Fluorimetric detectors are much more sensitive than UV detectors whereas electrochemical detectors are as selective (by selecting the characteristic potential of the analyte’s redox couple), although expensive and delicate. Derivatization with dansyl- or p-phthalaldehyde (OPA) is often carried out in order to achieve more selectivity and sensitivity. Either group with good fluorescence properties or a halogen atom that makes the analyte itself fluorescent can be inserted in the molecule, but because these groups increase the molecular dimensions,
thus minimizing the differences between the analytes that have to be separated, it is necessary to perform the derivatization after each molecule has been eluted from the column and has been separated from the others. Precolumn derivatization is also used, but although postcolumn(73) derivatization involves the use of additional devices it gives better selectivity.

HPLC has been interfaced with MS spectrometers (liquid chromatography/mass spectrometry (LC/MS)) allowing the application of such detectors to heavy molecular weight or labile molecules. A review of the application of LC/MS to the analysis of pesticide residues, drugs and mycotoxin in food was published by Careri et al.(74)

2.3.2.3 Qualitative Identification and Confirmation of Residues All the chromatographic methods generally identify the respective analytes by the time it takes for elution of each compound from the column within the definition of absolute and relative retention time. However, because of potential interferences from the matrix and the possibilities of coelution of different molecules, whatever column is used, some confirmation by an alternative instrumental technique, detector or method is needed. The confirmation becomes a “must” when a residue is found to be over the active limits stated by regulation.

The most widely used and selective technique used to confirm results is a MS detector coupled to a gas chromatograph. The whole mass spectrum is a unique fingerprint of the compound detected which provides the best confirmation but unfortunately it is not always possible to acquire the whole mass spectrum down to levels of 0.1–0.05 µg mL⁻¹ of sample extract. Therefore selected ion monitoring (SIM) choosing the three–four most specific fragments (see also Table 1) must be used.

For confirmation by GC/MS the chosen fragment must have a m/z value (when possible) over 100. Further confirmation can be obtained when the residue found exceeds the active limit (or maximum residue limit (MRL)), by comparing abundance ratios of the acquired ionic fragments, which must fit those of the standard within a tolerance of ±20%.

In other cases useful confirmation can also be obtained with the same detector and a different polarity column. Confirmation can also be obtained for some compounds that respond to more than one detector by comparing chromatographic runs with NPD/FPD and ECD detectors. HPLC with UV or fluorimetry detection can also be used for this purpose. DADs which acquire the whole UV spectrum, also provide a fingerprint of the eluted compounds.

More and more applications have been published concerning the use of tandem GC tandem mass spectrometry (MS/MS) where an ion selected from the spectrum produced by the first mass spectrometer is fragmented into a second mass spectrometer with a greatly enhanced selectivity. The availability of relatively low cost instruments based on the ion trap will make probably MS/MS the main technique(75) for residues confirmation in the future.

2.3.2.4 Quantitative Determination Quantitative determinations, as in all chromatographic methods, are made by comparison of the analyte’s peak with a peak from standard solution of known concentration. Owing to the usually very low volume injected in GC (1–2 µL), errors in measuring this volume can occur, and the use of internal standard can automatically correct these errors. On the other hand, in HPLC, since loop valves always inject the same standardized amount of sample (10–100 µL), the column does not need an internal standard. The use of an internal standard also corrects for cases where variations in the absolute response given from detector are caused by uncontrolled phenomena. Instrumental errors in the 5–15% range are common for external standard quantitations, and use of an internal standard can decrease this error down to 5–2%.

Calibration can also be performed on the matrix extract or by addition to the sample in order to take account of the potential effect of the matrix (see below).

In quantitation performed with GC/MS instruments it is recommended that as large m/z values as possible for the fragments be chosen so that less interference can occur from the matrix. Another method used in GC/MS quantitation is isotopic dilution,76 where an isotope-enriched standard for the compound being investigated is added to the sample giving rise to a change in the isotopic ratio from which the concentration of the compound can be calculated.

Since the cleanup step normally does not remove all the matrix, the organic matter in the extract that is present in concentrations greater by orders of magnitude than those of the pesticides investigated, may interfere heavily with the instrumental determination of some molecules. This happens especially in GC multiresidue techniques where the matrix progressively dirties the column during use. Some pesticides are quite labile (e.g. captan, captafol, diozof, pyrethroids, N-methylcarbamates, o,p-DDT) and undergo partial degradation during the gas chromatographic run, whereas other molecules (i.e. acephate, metamilofos, vamidothion, methomyl and other N-methylcarbamates) strongly interact with active sites created in dirty used columns with peak broadening and decrease in sensitivity. Thus when a standard pesticide mixture in pure solvent is injected, peaks corresponding to the active molecules cited above are
broadened or are not detectable especially at low concentrations 0.1–0.5 µg/mL. The so-called “matrix-effect” works so that, at the same concentration, in the presence of the matrix, the coextracts saturate the active sites in the column or in the liner and the pesticide can be observed with its whole peak intensity. On the other hand, in the absence of the matrix, the pesticide interacts with the column (or liner) active sites bringing about peak intensity reduction and consequent overestimation of the data. These effects are sometimes not in evidence because the overestimation produced by the matrix effect goes to balance a recovery under 100%, whereas in some cases recovery values over 200% are produced; some papers report studies characterizing the matrix effect. To take into account this phenomenon, which is particularly severe in the case of cold-on-column injections it is necessary: (1) to have a guard column of 2–5-m length that can be periodically changed, (2) to change the liner insert in the injector if present, and (3) to perform the calibration in the same (or closest) matrix extract as the sample, even for those active molecules for which this effect produces recoveries (or closest) matrix extract as the sample, even for those active molecules for which this effect produces recoveries of >120%. Kocourek et al. studied the stability of standard solutions in extracts and they found that at 20 °C, over a two-month period, degradation of several pesticides was observed, so that storage of sample and calibration extracts in a freezer is recommended.

2.3.2.5 Determination of Metabolites In many cases the active molecule originally sprayed on the plant may not be the only residue to look for because degradation on the plant and metabolism in animal tissues originates new products. In some cases these metabolites exhibit similar or more toxicity with respect to the parent compound (e.g. DDE and DDD from DDT). Table 2 lists the main metabolites for some active molecules. The metabolites in most cases are extracted together with the active parent molecules by the multiresidue methods according to the capability of the method to extract large spectra of different organic compounds and classes. Information about pesticide metabolites, their fates and relative studies are also available in book series such as Reviews of Environmental Contamination and Toxicology. Other information about methods for metabolites can also be found in the report series Pesticide Residues in Food by Joint Meeting for Pesticide Residues (JMPR) which reports the trials performed worldwide in order to assess the residue levels for a given active molecule in each commodity and for each country following good agricultural practice (GAP).

A particularly well-studied metabolite is ethylene-thiourea (ETU) from the degradation of ethylencylenes- and propylenebis-dithiocarbamate fungicides either on plants or during food processing; this is a case when the

THI, tetrahydrothiophalide; DCBF, dichlorobenzophenone; PTU, propylenethiourea.

Table 2 Main metabolites of some pesticides

metabolite is more toxic than the parent compound. ETU must be derivatized in order to make it detectable well by GC. Dubey et al. recently proposed a double step
derivatization method with benzyl chloride, followed by LLP, and then with TFA and double detection by ECD and NPD.

2.4 Special Methods for Specific Classes

2.4.1 Gas Chromatography Headspace Methods

2.4.1.1 Fumigants Although official methods for fumigants in grains still use extraction with solvents, some methods\(^{84,85}\) have been developed using headspace techniques, relying mostly on the high volatility of the compound investigated. OC fumigants, e.g. are not different from the volatile organic compounds (VOCs) analyzed in water samples by headspace methods. Headspace methods require less preparation of the sample and have less risk of analyte losses.

2.4.1.2 Dithiocarbamates Dithiocarbamates are usually detected by headspace methods as total carbon sulfide, after reduction with tin(II) chloride in acid medium. General purpose columns for VOCs are used with ECDs or FPDs (sulfur mode).\(^{86}\) These methods are fast and allow analysis of much more sample at the same time than with colorimetric methods (see below).

2.4.2 Ultraviolet/Visible Colorimetric Methods (Dithiocarbamates, Phosphine) Ultraviolet/visible (UV/VIS) colorimetric methods are based upon selective reaction with a chromogenic reagent and a single pesticide (or class of pesticides) to give a colored adduct that is spectrophotometrically measurable. Obviously colored substances from the vegetable and coextracted substances that may react with chromogenic reagent may cause interference. Some methods that provide isolation of the analyte by distillation or degradation into other products are more or less widely used.

2.4.2.1 Methods for Dithiocarbamates A dated method that is still widely used is that by Mestres\(^{87}\) where dithiocarbamates are reduced to carbon sulfide by heating the sample in the presence of tin(II) chloride and potassium iodide, in an acidic medium. The carbon sulfide developed is fixed by chromogenic reagent (copper acetate, diethanolamine in ethanol) as copper dithiocarbamate and measured spectrophotometrically at 435 nm. Two traps (sodium hydroxide for acidic substances and zinc acetate for bases) must be inserted before chromogenic reaction to avoid interference. Naturally producing carbon sulfide substances can give noticeable interference or false positives (rocket, capers, cabbages).

Methods that distinguish between single dithiocarbamates compounds are not widely developed. Some methods are proposed for thiram and ziram in the FDA Pesticide Analytical Manual Vol. 2\(^{15}\) and for thiram by Ekroth et al.\(^{88}\)

2.4.2.2 Methods for Phosphine Phosphine can be distilled from treated commodities in the presence of concentrated sulfuric acid, transformed into orthophosphate anion by oxidation with bromine\(^{89}\) or potassium permanganate\(^{90}\) and detected spectrophotometrically by methods used for phosphates. Alternative simple methods measure phosphine by direct reaction\(^{91}\) with silver nitrate giving a yellow complex in methanol.

2.4.2.3 Methods for o-Phenilphenol and Biphenyl An old method\(^{92}\) measures these compounds by refluxing an acidified sample with apposite apparatus (Clavenger) and the distilled pesticide residues are collected in 5–10 mL of hexane floating on the condensed water. Pesticides extracted can be determined either by UV/VIS spectrophotometric methods or by chromatographic methods.

2.4.3 Atomic Absorption Methods (Inorganic and Organometallic Compounds) Atomic absorption methods do not differ from those used in assessing metal trace levels in food (see Atomic Spectroscopy in Food Analysis). A limiting factor may be the natural content of a given metal in a crop, which may originate from a pollution history in its own soil, so that the pesticide levels to be detected are lower.

Modern inductively coupled plasma atomic emission spectrometry (ICPAES) can determine elements other than metals such as phosphorus. An example for phosphine/orthophosphate is given by Mortensen et al.\(^{90}\)

2.4.4 Immunoenzymatic Methods and Other Methods Immunoenzymatic techniques are less used methods and are mainly used in screening. Many of them detect the function characteristics of given groups (e.g. triazines. OC, organophosphates) without discriminating between the single compounds in the class and are therefore of less interest because residue limits are fixed for each compound by regulatory acts. More selective methods known as enzyme-linked immunosorbert assay\(^{28,93}\) (ELISA) based on the reaction of a pesticide-horseradish peroxidase (HRP) conjugate with a monoclonal or polyclonal antibody have been developed. The ELISA method allows determination of specific compounds at parts per trillion levels. The main advantage of these methods are that they are less time-consuming, analysis is in situ, and they have high sensitivity and specificity. More information is available elsewhere.\(^{94–98}\)

Another technique that must be taken into account is thin-layer chromatography (TLC), which despite
the many advances that have been brought about by more sophisticated techniques like GC and liquid chromatography has remained a useful technique for screening and quantitative analysis in the field of pesticide residues. A comprehensive and synthetic review has been published by Rathore and Begum where stationary phases, mobile phases, detectors and other details are tabulated. Silica gel is the stationary phase used most, while hexane, chloroform, acetone, and other solvents in many different combinations are used as eluents. Detection is by means of reflectance densitometers or characteristic reaction of a single or a class of compounds (e.g. cholinesterase for organophosphates). Rathore and Begum also published an interesting study where different stationary and mobile phases and the relative effects on the separation of a class of compounds (carbamate) were tested.

The advantages of TLC are that it is a simple technique, not requiring sophisticated instruments, so that every laboratory can use it.

3 MYCOTOXINS

3.1 Problem of Mycotoxins in Food

Apart from the problem caused by the widespread use of pesticides and their residues, in commodities (mainly cereals and fruits) infected by a particular species of fungus, the metabolic activity of the mold gives rise to substances known as “mycotoxins”. Mycotoxins are characterized by their acute toxicity and carcinogenicity which is on the same level as most toxic pesticides. Mycotoxins that are present in commodities stored in moist conditions can injure animals given contaminated feed (e.g. “turkey’s X disease” in Great Britain or “porcine nephropathy” in Denmark) or people (e.g. “Balkan endemic disease” in Southern Yugoslavia).

3.2 Different Types of Mycotoxin

The mycotoxins are metabolites originating from particular species of fungi and molds. Their structures are mostly based on condensed heterocycles bearing mainly oxygen as heteroatom and –OH, >C=O and esterified functions. In this section the most relevant molecules that are usually sought in food will be briefly described.

3.2.1 Aflatoxins

The aflatoxins are among the most toxic and carcinogenic mycotoxins and are produced by two species of Aspergillus (A. flavus and A. parasiticus). These molecules are derived from heterocycles and their structures are shown here; several species of aflatoxin named B₁ [CAS 1162-65-8] (1), B₂ [CAS 7220-81-7] (2), G₁ [CAS 1165-39-5] (3), G₂ [CAS 7241-98-7] (4), M₁ [CAS 6795-23-9] (5) and M₂ [CAS 6885-57-0] (6) exist. Other secondary metabolites have also been identified like aflatoxicol, dihydroaflatoxicol and aflatoxins P and Q.

Aflatoxins are characterized by fluorescence ranging from green to violet. Aflatoxins B and G are usually found on contaminated moldy cereals, cotton, and peanuts used either as food or as animal feed. Aflatoxins M1 and M2 are metabolites found normally in the milk of animals who have ingested contaminated feed. Species B and G are very toxic with LD₅₀ values ranging from less than 0.5 to near 20–30 mg kg⁻¹ body weight. These molecules are particularly dangerous for the liver and can also damage the immune and reproductive systems; other effects observed in animals were a reduction in consumption of feed and in production of milk. Carcinogenic effects were observed in experimental animals given contaminated feed at levels ranging from a few to tens of micrograms per kilogram and with induction times from one to two years. Mutagenic activity seems to be in relation to the ability of the molecule to interfere with DNA synthesis.

3.2.2 Ochratoxins

Ochratoxins are toxins produced from Aspergillus ochraceus and other species of Aspergilli and Penicilli; they originate from biosynthesis from phenylalanine and dihydrocoumarin moieties.

(differing from the species A as not being chlorinated) and ochratoxin C [CAS 4865-85-4] (9) (the ethyl ester of species A); all these molecules exhibit a blue-greenish fluorescence.

\[
\begin{align*}
\text{(7) Ochratoxin A} & \quad \begin{array}{c}
\text{COOH} \\
\text{N} \\
\text{H} \\
\text{Cl} \\
\text{CH}_3
\end{array} \\
\text{(8) Ochratoxin B} & \quad \begin{array}{c}
\text{COOH} \\
\text{N} \\
\text{H} \\
\text{CH}_3
\end{array} \\
\text{(9) Ochratoxin C} & \quad \begin{array}{c}
\text{COOEt} \\
\text{N} \\
\text{H} \\
\text{Cl} \\
\text{CH}_3
\end{array}
\end{align*}
\]

The ochratoxin A (7) is well known as a very toxic molecule with LD$_{50}$ values being very close to those characteristic of the aflatoxins; it has been found on coffee grains and moldy cereals. Ochratoxins A (7) and B (8) are characterized respectively by green and blue fluorescence.

### 3.2.3 Patulin

Patulin [CAS 149-29-1] (10) is produced from *Aspergillus*, *Penicillium* and *Byssochlamis* and affects mainly fruits, where inadequate collecting (tumble shocks) and storage (moisture) conditions favors rotting and consequent mold growth. Apple is particularly attacked by molds producing this toxin and residues of patulin are also found on fruit juices and ciders. The chemical formula of patulin (10) is shown.

\[
\text{(10) Patulin}
\]

At toxic levels patulin can originate gastrointestinal diseases and can also damage the spleen, kidneys and lungs as demonstrated by experimental animals. There is also some evidence of teratogenicity and possible carcinogenicity. Typical LD$_{50}$ values (e.g. for rat) range from 10 to 50 mg kg$^{-1}$ body weight. Its carcinogenicity may originate from the conjugated double bond system present in the molecular structure.

### 3.2.4 Trichothecenes, Fumonisins and Zearalenone

These molecules are all produced by several species of *Fusarium* and other fungi (*Trichothecium, Stachybotrys* etc.). Trichothecene toxins cover a wide group of molecules (over 40) based on the structure of another mycotoxin, the trichothecin [CAS 6379-69-7]. Trichothecenes may be divided between two main groups: the nonmacrocyclic trichothecenes and the more labile macrocyclic ones that can be considered to be polyesters of simple trichothecenes. Among the best known trichothecenes are nivalenol [CAS 23282-20-4] (11), deoxynivalenol (DON, named also “vomitoxin”) [CAS 51841-10-8] (12) and 3-acetyldeoxynivalenol (13), neosolaniol [CAS 36519-25-2] (14), T$_3$ [CAS 21259-20-1] (15) and HT$_2$ [CAS 26934-87-2] (16) toxins, verrucarol, scirpentriol (17), diacetoxyscirpentriol (DAS) (18), 15-monoacetoxyscirpentriol (19) and fusarenone [CAS 3255-69-8] (20). Among macrocyclic trichothecenes there are the H (21) and G (22) satratoxins, roridin A (23) and verrucarin A [CAS 3148-09-2] (24). Schemes 1 and 2 show the chemical formulas of nonmacrocyclic trichothecenes, whereas Scheme 3 shows chemical formulas of some macrocyclic trichothecenes.

Trichothecenes and zearalenone [CAS 17924-92-4] (25) are found on moldy cereals. Generally the trichothecenes affect the immune system so that targeted animals or humans become more subject to infections. Symptoms of severe intoxication in man are vomiting, fever, headache, skin irritations, respiratory disorders and diarrhea.

The nivalenol (11) and DON (12) vomitoxins are known to cause refusal of food, vomiting and subsequent weight loss together with diarrhea and other gastroenteric diseases in animals given infected feed; in the most severe intoxication damage to kidney, stomach and heart can also occur both in animals and in humans. T$_3$ (15) toxin is very toxic (LD$_{50}$ orders range from near 1 to 5 mg kg$^{-1}$ body weight) and injures the digestive apparatus and reproductive system.

Zearalenone (25) is a toxin produced over a quite wide range of temperatures (about 10–30°C). Its activity is based on estrogenic action causing diseases to male and female genital apparatus. The chemical formula is shown by structure (25) and that of zearalenol by structure (26).

Fumonisins (B$_1$, (27); B$_2$, (28); B$_3$, (29)) are recently discovered mycotoxins produced from *Fusarium moniliforme*. Fumonisins are now known to cause leukoencephalomalacia in horses or pulmonary edema in swine and is suspected to cause esophageal cancer in humans.

3.2.5 Toxin from Alternaria and Others

*Alternaria* fungi, in particular *Alternaria alternata* are known to produce, as a result of their metabolism, some...
molecules (alternariol [CAS 641-38-3] (30), alternariol methyl ester [CAS 23452-05-3] (31), altenuene (32), tenuazonic acid [CAS 610-88-8] (33)) that have shown some evidence of mutagenic and carcinogenic activity towards animals. Molecular structures of these molecules and altenuxin I (34) are shown. Mycotoxins from Alternaria have been found in degraded vegetables, seeds and cereals.

Among the other mycotoxins, of noticeable importance are sterigmatocystine and citrinin [CAS 518-75-2] (35). Sterigmatocystine is produced from different species of Aspergillus and is believed to be a precursor of the aflatoxins; the molecular structure is similar to that of the aflatoxins and this molecule also exhibits hepatotoxicity, kidney toxicity and carcinogenic activity. Citrinin (35) is often found together with ochratoxins in moldy cereals and like ochratoxins it exhibits toxicity towards the kidney.

3.3 Methods of Analysis

Like pesticides, a large number of articles have been published on mycotoxins covering many different experimental conditions both in the preparative step and in instrumental detection and this is reflected in the different values of sensitivity (LODs) reported in different papers.

Official methods are generally available for mycotoxins (101). Furthermore, several reviews or papers covering general or particular topics in mycotoxins residue analysis in food have been published. Reviews concern aflatoxins (103) analysis of residues in milk (104), mycotoxins (105) with COOH groups, chromatographic methods (106) for ochratoxin A, fumonisins (107) or others (108) use of immunoaffinity (109) columns, high-performance TLC (110) for aflatoxins and TLC (111) for mycotoxins, applications with HPLC/MS (112) systems, methods for nonmacrocyclic (113) trichothecenes, and sample preparation (113, 114).

Owing to the extreme toxicity of some mycotoxins, pure standards for aflatoxins and ochratoxins, for example, are available only on the milligram scale with unknown purity; therefore concentration of these standard solutions must be determined by spectrophotometry using extinction coefficients and their purity assessed by TLC, see also AOAC (101) methods 970.44 and 971.22.

3.3.1 Sample Preparation

3.3.1.1 Sample Extraction Owing to the polar characteristics of the molecules, extraction of the mycotoxin from the matrices is usually carried out with polar solvents including water, methanol, acetonitrile, acetone, chloroform and their mixtures. The weighed amounts for extraction vary from 10 g to near 100 g with the obvious effect on the final detection limits. In some cases amounts of the magnitude order of kilograms are extracted, taking into consideration that the toxin distribution in the commodity is very heterogeneous.

In some cases, e.g. dry cereals, the sample is blended with water prior to extraction in order to homogenize it and to make the analyte more extractable.

Typical extraction mixtures for aflatoxins, ochratoxins, fumonisins and trichothecenes from cereals and seed are water–acetonitrile with ratios from 2:3 to 1:9 and water–methanol with ratios from 1:1 to nearly 9:1; acetone with a low percentage water content and water nonmiscible solvents like dichloromethane, chloroform or the less harmful ethyl acetate are also used (108). For trichothecenes the extractant most used (112) is acetonitrile–water in the ratio 86:14.

Extraction with an aqueous/organic phase needs to be filtered in order to eliminate water-insoluble substances. Several papers report the use of solutions of acetic acid, sodium chloride, and zinc or lead acetate to aid in defatting the extract by precipitating fatty acids as metal soaps. Defatting of the extract by extraction with nonpolar solvents like hexane, heptane or petroleum ether, where polar mycotoxins are practically insoluble, has also been achieved.

In some cases aqueous solutions of sodium hydrogen-carbonate (≈1–3%) are used as extractants (115).
Extraction of aflatoxins from milk samples often requires a less complicated preparative step and can be defatted simply by centrifugation, aided by addition of some sodium hydroxide or sodium chloride, and the remaining aqueous sample extracted either by partition with chloroform or by adsorption with SPE or onto an immunodiffusion cartridge.

Methods for ochratoxin often report use of partition with chloroform or methylene chloride and aqueous phosphate buffer.

Applications of direct ochratoxin extraction from beer by passing through a C_18 SPE cartridge are also reported. A German method extracted ochratoxins from wine using toluene with added magnesium chloride at pH 2.

Patulin from ciders and juices is generally extracted, owing to aqueous nature of the sample, with ethyl acetate, which is nonmiscible with water, followed sometimes by partition with sodium hydrogen carbonate aqueous solution.

SFE, as a technique recently introduced and requiring sophisticated and expensive apparatus, is used less. Applications are reported for extraction of DON and some others trichotheccenes operating at 40–60 °C and 300–500 bar with carbon dioxide containing 3–5% methanol on 1–5 g of sample. Extraction can be achieved either statically or dynamically, in less time (e.g. 15 min instead of 30 min). A review concerning uses of SFE in extracting flavors, lipids fragrances and mycotoxins from natural products was published by Modey et al.

3.3.1.2 Sample Cleanup Cleanup onto solid substrates is normally achieved on silica or other substrates like Celite, Florisil, or alumina. The sample extract applied onto a silica column is washed with apolar solvents like hexane or diethylether, whereas the elution of the mycotoxin is carried out with chloroform (or dichloromethane) containing some 1–10% of acetone or methanol to increase the polarity of the medium. Widely used multifunctional columns (Mycosep) consist of different stationary phases with alumina, Celite, charcoal and ion exchangers which retain substances from the matrix when the water–acetonitrile extract is simply passed through.

The use of SPE columns involves silica, C_18 octadecylsilica or phenylsilica functionalized stationary phases, where the applied sample is eluted with chloroform (or dichloromethane) with about 10% acetone; ion-exchange stationary phases (e.g. Amberlite XAD, strong anion exchange (SAX)) are also used in SPE cleanup.

Immunaffinity columns (IAC) represent a technique of purification and/or separation and preconcentration which is very selective, based on the interaction between the mycotoxin and a specific toxin antibody linked to a solid substrate. Usually before the cartridge is loaded with the sample (the extract concentrated in methanol, acetone or acetonitrile must be diluted), it is washed with a buffered saline solution (e.g. phosphate buffered saline (PBS) containing a surfactant, such as tween-20). The sample is then adsorbed and washed with PBS buffer, water or aqueous 10% methanol. The mycotoxins are finally eluted with methanol or aqueous methanol (e.g. 80%) solutions or acetonitrile. Some commercial specific cartridges are now available, for example for aflatoxin, ochratoxins, fumonisins and zearealenone. The advantages of this type of cleanup come from its selectivity whereas disadvantages are the high cost of a single column and the nonavailability in commerce of “multitoxin” columns performing SPE in the multiresidue methods.

Comparisons between different cleanup and extraction techniques have also been published: e.g. multifunctional columns, IAC and SPE techniques, or IAC versus solvent extraction techniques where the latter (with ethyl acetate) showed less capacity for extraction.

Finally, in the same way as already seen for pesticides, the organic extract can also be purified by GPC.

3.3.2 Instrumental Methods

3.3.2.1 Gas Chromatography and Gas Chromatography/Mass Spectrometry Techniques GC is not extensively used in analysis of mycotoxins due to the characteristics of the molecules (relatively high-molecular weight, high-melting point and the presence of strong intermolecular interaction due to polar function like –OH, C=O and –COOH groups) that make them unsuitable for such instrumental analysis. Derivatization techniques must be used in order to make the molecule more volatile so that the temperature and time needed to elute the compounds from the column are not too great.

Most applications found in the literature are for trichotheccenes and zearealenone but applications for patulin, alternaria toxins and aflatoxins with short columns have also been reported. Hexpfluorobutyric acid (HFBA), TFA and heptafluorobutyrylimidazole are typical derivatizing agents that insert fluoro-substituted groups into the molecules by esterification of their OH functions. Silylating reagents like bistrimethylsilylacetamide (BSTFA), trimethylsilylimidazole and trimethylchlorosilane are other derivatizing agents. The latter two in particular are used to ensure complete silylation because of the difficulty of silylating some functions arising from double peaks (two silylated products) in the chromatogram.

A general oven temperature program runs from 80–100 °C up to 140–210 °C at 10–20 °C min^{-1} and then
up to 280–310°C at various rates from 5–10°C min⁻¹. Capillary columns up to 50-m long are used but mostly columns 15–30-m long are used. The columns are coated with 100% methylsilicone or containing 5% phenylsilicone, 6–14% cyanopropylphenylsilicone or other phases.

Detectors used are FID, ECD and MS in GC/MS (electron impact (EI), chemical ionization and negative ion). In GC/MS systems it is necessary to operate SIM to achieve the required sensitivity. In the case of mycotoxin, ions of TMS (trimethylsilyl), TFA or HFBA derivatives are usually collected. Derivatives are also characterized by fragments with greater values of m/z so that fewer undergo interference from the matrix. In Table 3 some characteristic ions of toxins or their derivatives are shown.

The FID is not very sensitive and sensitivities of the order of 0.1–1 mg kg⁻¹ are reported even with the use of derivatizing agents. More selective and sensitive detectors like ECD or MS allow detection limits in the range 0.01–0.05 mg kg⁻¹ to be attained.

### 3.3.2.2 High-performance Liquid Chromatography and Liquid Chromatography/Mass Spectrometry Techniques

HPLC analysis of mycotoxins is usually performed by reversed-phase liquid chromatography; the columns most used are 25-cm long (4.6-mm diameter) and have C₁₈ octadecylsilane functionalized silica (ODS) as stationary phase. Columns used to a lesser extent are C₃ columns and 10, 12.5 and 15 cm-long columns. Methanol–water (40–80% methanol) or methanol–acetonitrile–water in various ratios are used as mobile phases also with aqueous phase containing 1–5% acetic acid, phosphate buffers or other buffers depending on the method.

Detection is mostly based on the fluorescence properties of the molecule (as is the case for example for aflatoxins, ochratoxins and fumonisins) by fluorimetric detectors working in the range 330–380 nm for excitation wavelength and in the range of 420–460 nm for emission wavelength; in other cases UV detection is used with DADs. Derivatization is often performed in order to enhance the detection, either by pre-column derivatization with TFA, boron trifluoride, phenilendiamine, OPA (for fumonisins) or by postcolumn reaction with I₂ or Br₂. Some authors studied the effect of detection enhancement originated by cyclodextrins. Limits of detection are strongly related to the preparative route in addition to the instrumental conditions used, in particular the amounts of sample extracted and the final volume of the extract. Limits of detection ranging from a few nanograms per kilogram (for aflatoxins) to micrograms per kilogram for less detectable fumonisins, trichothecenes and zearalenone. For patulin LODs of tenths of micrograms per kilogram are normally reported.

Chromatograph from HPLC have been interfaced with mass spectrometers by means of apposite devices that eliminate a large amount of interference due to the solute being in the mobile phase (e.g. buffers, salts). Electrospray and thermospray devices are usually used as interfaces, electrospray being preferred as they give more abundant molecular ions than do thermospray giving more fragmentation with APCI or EI. Ionization in the negative ion mode gives better sensitivities than ionization with positive ions. As in GC/MS systems, operating in SIM allows greater sensitivity; in Table 3 some examples of ions that characteristically have toxins as parent molecules or as derivatives in different LC/MS or LC/MS/MS systems are reported.

#### 3.3.2.3 Capillary Electrophoresis Techniques

Relatively few papers report on this topic. Separation of mycotoxins is generally performed on 50–75-cm long capillary silica columns with diameters ranging from 50 to 75 µm. The potentials applied vary from 10 to 20 kV with 50–70-cm distances from anode to detector. Detection methods used are UV/VIS/DAD, conventional and laser-induced fluorescence. Derivatization and hydrodynamic system of injection at high pressures are used for more sensitive determinations.

#### 3.3.2.4 Other Techniques

**Thin-layer Chromatography.** A multiresidue method determining 22 mycotoxins simultaneously by TLC has been published. TLC is a quite simple method that does not require sophisticated instruments but, owing to the complexity of the sample and the low levels investigated, still requires the preparative step of cleanup of the sample like those described above. TLC separations are mostly performed with silica as stationary phase whereas a very great number of solvent mixtures and reagents are used respectively as eluents and as detecting agents. Quantitation is made by spotting different amounts of sample and standards on the plate and matching the intensity of the respective spots to assess which spots exhibit the same intensity of response.

The review by Ling et al. also compares TLC with other methods. TLC is a very simple technique having sensitivity and precision similar to the HPLC method whereas ELISA is less reproducible.

#### 3.3.3 Immunochemical Methods

Radioimmunnoassay (RIA) is a technique not widely adopted in mycotoxin analysis, while ELISA tends to substitute for RIA because the former is a simpler and safer method (handling of harmful radioactive substances is avoided). ELISA measures mycotoxin levels by competition of the analyte and its analogs conjugated with an

APCI, atmospheric pressure chemical ionization; API, atmospheric pressure interface; HFB, hexafluorobutyl.

enzyme molecule, for the site on an antibody immobilized on a solid support (membrane, test tube, microtiter well plate and so on). The enzymatic activity is related to the toxin–enzyme conjugate present on the antibody, whose presence is also related to the free mycotoxin (the analyte) present. The enzymatic activity is measured simply, after washing the solid support with a saline buffered solution (also added with a surfactant, e.g. Tween), by adding the enzyme substrate and a chromogenic solution. A typical enzyme is HRP with a chromogen like \(o\)-phenylenediamine or tetramethylbenzidine; the absorbance of the solution is read on a spectrophotometer at 440–490 nm. These methods are now also available in commercial prepared kits and are as sensitive as RIAs but simpler and cheaper and allow the operator to avoid handling radioactive isotope solutions. Sensitivities for ELISA range from less than 0.1 to 50 \(\mu\)g L\(^{-1}\).

4 QUALITY CONTROL

4.1 Validation of Method and Internal Laboratory Quality Control

Analytical methods can be regarded as transformation processes where the end products are the data. The quality of data and thus reliability of the methods must be assured by a series of experimental steps in what is called “validation”. Some aspects must be characterized and some parameters must be defined experimentally as stated in the EN45001\(^{144–147}\) regulation.

The linearity of the analytical response of the method must be checked by increasing the analyte concentration. In doing this, the fact that the different detectors may not have a linear response over the usual range covered by the residues (more or less than 0.001–10 mg kg\(^{-1}\)) must be taken into account. The first step is to study the instrumental response, followed by a more severe approach which includes the preparative step in the linearity study so that the overall measured linearity is accurate with a precision calculated at different (usually from three to five) concentration levels of the analyte. All such work takes a great deal of time and effort especially in the case of a multi-residue method, and thus must be adequately planned.

The accuracy is assessed either by determining recoveries on added matrices in the laboratory or less frequently by analyzing reference materials, whereas precision is assessed by repeating the analysis on the same sample from five to eleven times. The preparative route for this type of analysis greatly affects the data in terms of accuracy and precision. Precision\(^{148}\) depends on the potential of many random errors at every step; accuracy depends on sample losses from the several preparative (negative) steps or from matrix effects (positive). Usually accuracy and precision are determined at the same time by repeated analysis on fortified matrices. In the field of pesticide residues reference materials are rare and expensive due to complexity of preparation and instability, on the other hand, in the field of mycotoxins, reference materials, although expensive, are very important.

A reference material for residues analysis must always be stored at low temperature (\(\leq 25^\circ\)C). Other methods of checking accuracy and precision are by participating in proficiency tests and collaborative/cooperative trials. Recently some organizations that have performed proficiency tests make test materials available after each set have been performed and the average consensus value for added analytes (normally from 3 to 6) has been assessed.

The identification of a compound must always be confirmed by another detection technique or another method. GC/MS and LC/MS or at least HPLC/DAD (with acquisition of the whole UV spectrum) are the
instruments used most. If SIM/GC/MS (or SIM/LC/MS) is used, the acquisition of the whole mass spectrum or at least three characteristic ions with \( m/z \) values \( > 100 \) (when possible) is recommended when residues found exceed the active limits.

Quantitation must be performed with appropriate calibration with at least two calibrating points “bracketing” the concentration found in the sample; if single point is used, it should not exceed \( \pm 25\% \) of the value of the sample. Calibration must also take into account matrix effects described above. Limits of detection must be checked with respect to recovery from the matrix and not only with respect to instrumentation.

Blanks of the entire procedure are recommended because the quality of materials (solvents, salts) may not be constant at the time and fine cleaning of the glassware with pure solvents must be assured before each analysis.

Instrument calibration and performance must be checked at regular intervals (e.g. once for each group of samples analyzed) following manuals and good laboratory practice principles; instruments used in preparation must be also controlled, e.g. GPC cleanup systems must be checked for recoveries and cleanup power by eluting special sample mixtures or by simply testing recovery of some pesticides (chosen between those with higher and lower retention volumes) and their purification from the matrix.

It is recommended that both the laboratory and the instruments used in preparation be dedicated to this kind of analysis; the original samples and their extracts must be kept separate from the pure standards and their concentrated and diluted solutions. All items must be stored at a low temperature in a refrigerator or freezer. Studies concerning standard solutions stability with respect to solvent and storage conditions used have been published.\(^ {149}\)

Control charts are not easy to prepare for such a complex analysis, however the performance of the method can be checked by inserting into each sample batch of 20–30 analyzed samples a blank sample and a fortified sample to check for interferences and analysis recoveries. For common pesticides it is recommended to check the recovery in every sample batch frequently, whereas for rare pesticides a yearly recovery test is adequate. It may be the case that for pesticides of the same class and which exhibit the same behavior, a recovery test performed on selected molecules may be indicative of all the pesticides in the class.

### 4.2 Interlaboratory Quality Control

Quality control programs performed by a laboratory undoubtedly greatly enhance the reliability of the data produced from that laboratory; however interlaboratory tests present a more powerful system for assessing the ability of one or more laboratories to produce true data. Such trials acquire importance particularly with respect to official programs for monitoring residues to establish knowledge about the contamination status of food and the undesirable persistence of some active molecules.

Among interlaboratory tests are intercalibrations, collaborative/cooperative studies and proficiency tests.

Intercalibrations may even be simple exercises where matrices which have known substances added at unknown level (or even standard solutions in the simplest trials) are distributed among several laboratories. On the basis of the data reported, the accuracy and the precision of the testing group of laboratories can be established. Several examples have been reported.\(^ {150,151}\)

More sophisticated studies are collaborative (several laboratories using the same methods) and cooperative (several laboratories using their own methods) performed by each laboratory to give a series of samples at different fortification levels, in duplicate. Each trial may be repeated a number of times during a specific period (e.g. six months, one year). In this case too, known compounds but at unknown levels are quantified, see cited examples.\(^ {120,124,152–155}\)

On the other hand proficiency tests are spot exercises where the ability both to identify given compounds to quantify them is evaluated. In these exercises a fortified matrix with between four and six unknown compounds at unknown levels, chosen from a list of some 20–50 known compounds, is distributed to several laboratories. These have to discover which pesticides are present and in what relative amounts. Results presented by each laboratory are compared with the medium values or the robust consensus mean value obtained from all the laboratories and the difference from it (z-score) is expressed in terms of Horwitz’s standard deviation\(^ {156}\) at that concentration level. Normally performances are considered acceptable where difference from the consensus means not exceeding two (or also three) times the Horwitz’s standard deviation. Several examples have been reported.\(^ {157,158}\)

A survey carried out on the results of many interlaboratory trials showed that although the averaged interlaboratory reproducibility is located between 15% and 20%, the distribution of single results recorded in each exercise can range\(^ {159,160}\) from less than 5% up to 50%. Proficiency testing is recommended in European Community guidelines\(^ {161}\) for pesticide residual analysis.

Pesticides, Mycotoxins and Residues Analysis in Food

81. Reviews of Environmental Contamination and Toxicology, Springer Verlag, New York.

147. S.A. Thorpe, S.L. Reynolds, 'Accreditation in the UK', *Peptides, Mycotoxins and Residues Analysis in Food*.

Proteins are an important fraction in most foodstuffs, ranging from 1.8% in roots and tubers up to about 25% in legumes. However, in foods they are present in a complex multicomponent matrix also containing water, lipids, carbohydrates, and some minor components, all of which might interfere during the analysis of proteins in foods. A whole variety of analytical tools for protein analysis are available to the analyst but not all of them are suitable for routine analysis procedures. This article will deal with some key analytical techniques in order to give an overview of possibilities and shortcomings of current techniques and some promising future trends. Well established methods are the Kjeldahl method, spectroscopy in the ultraviolet (UV), visible (VIS), and infrared (IR) ranges of the spectrum, chromatography, and conventional electrophoresis, while recent developments are to be found in the field of capillary electrophoresis (CE) and immunology. Since validation of methods and results are important features of today’s analysis, some attention is paid to the availability and use of reference materials.

Proteins are defined as complex polymers of amino acids, which are incorporated in a fixed sequence given by the information encoded in the DNA. They can vary in structure depending on their sequence of amino acids and chain lengths, thereby making possible a diversity of structures and functions. Proteins constitute the primary material of living organisms and actually every living organism can be considered as a source of protein.

The use of different protein sources can vary widely from one country to another depending on habits and traditions. Available protein sources can roughly be divided into two major groups: plant and animal proteins. A major portion of the world protein supply is derived from plant proteins such as cereals, legumes, and oilseed proteins. From an economic and quantitative point of view, the most important animal protein sources are muscle tissue, eggs, and milk. Cereal grains are of critical importance for humanity and are major foods in every country, either directly or indirectly as animal feeds. Analysis of cereal proteins is especially challenging to scientists owing to their complexity and heterogeneity. Proteins are important from a nutritional and technological point of view, they affect every property that characterizes a living organism, and they play different roles in the human body. Owing to their importance and because each protein or protein source has its own functional and nutritional characteristics, both protein analysis and amino acid analysis are often a prerequisite for the characterization of a food product.

Various techniques are available to quantify the total N and protein content in food products. In section 2, three classical procedures are discussed: Kjeldahl, IR spectroscopy, and dye binding. The Kjeldahl method is an important procedure, at the least as the most frequently used reference method. Also, many official protein determination methods include the Kjeldahl technique. IR spectroscopy and dye binding are used as common routine methods in the quantification of N compounds and protein. For the quantification of specific N and protein compounds, three different methods are discussed: electrophoresis, chromatography, and immunology. These techniques are very specific and find their application in, e.g. authenticity research, determination of nutritional values, and quality control. Several N and protein determination methods have been described in review articles.

1 INTRODUCTION

Proteins are defined as complex polymers of amino acids, which are incorporated in a fixed sequence given by the information encoded in the DNA. They can vary in structure depending on their sequence of amino acids and chain lengths, thereby making possible a diversity of structures and functions. Proteins constitute the primary material of living organisms and actually every living organism can be considered as a source of protein.

The use of different protein sources can vary widely from one country to another depending on habits and traditions. Available protein sources can roughly be divided into two major groups: plant and animal proteins. A major portion of the world protein supply is derived from plant proteins such as cereals, legumes, and oilseed proteins. From an economic and quantitative point of view, the most important animal protein sources are muscle tissue, eggs, and milk. Cereal grains are of critical importance for humanity and are major foods in every country, either directly or indirectly as animal feeds. Analysis of cereal proteins is especially challenging to scientists owing to their complexity and heterogeneity. Proteins are important from a nutritional and technological point of view, they affect every property that characterizes a living organism, and they play different roles in the human body. Owing to their importance and because each protein or protein source has its own functional and nutritional characteristics, both protein analysis and amino acid analysis are often a prerequisite for the characterization of a food product.

Various techniques are available to quantify the total N and protein content in food products. In section 2, three classical procedures are discussed: Kjeldahl, IR spectroscopy, and dye binding. The Kjeldahl method is an important procedure, at the least as the most frequently used reference method. Also, many official protein determination methods include the Kjeldahl technique. IR spectroscopy and dye binding are used as common routine methods in the quantification of N compounds and protein. For the quantification of specific N and protein compounds, three different methods are discussed: electrophoresis, chromatography, and immunology. These techniques are very specific and find their application in, e.g. authenticity research, determination of nutritional values, and quality control. Several N and protein determination methods have been described in review articles.

2 QUANTIFICATION OF TOTAL NITROGEN AND PROTEIN

Protein determination methods are classified in two groups: some methods determine the protein content
directly, while others determine total organic N which is taken to be equivalent to crude protein. Of the latter procedures, the most important technique is the determination of N by the Kjeldahl method. Direct protein determination methods include procedures such as IR spectroscopy, turbidimetry, fluorimetry, refractometry and polarography.\(^2\)

In indirect protein determination methods, the factors used to convert total organic N into protein are based on the average N content of proteins in particular foods. An important condition for the conversion of N into protein is that the food product may not include other N-containing matter besides protein. A number of conversion factors for different cereals and other products have been adopted by the Food and Agriculture Organization and the World Health Organization.\(^2\) Some other scientists criticized those factors and have published factors for a wide range of foods based on detailed amino acid analysis.\(^12\) Another list of conversion factors was given by Gaspar.\(^7\) If there is no specified conversion factor, the N content is multiplied by 6.25, a factor corresponding to an average protein N content of 16%. When quoting data on protein content derived from indirect protein quantification methods, it is required to report also the conversion factor employed.

In protein analysis, a frequent operation is the determination of the nonprotein nitrogen (NPN) content, or its separation from the “true protein” nitrogen. Not taking into account the NPN fraction can lead to an overestimation of the true protein content, e.g. in the case of milk by about 5–6%. The NPN generally includes peptides with molecular weight (MW) <10 kDa, free amino acids, ammonia, urea, and trimethylamine oxide. The methods most often employed to separate NPN are dialysis, ultrafiltration and precipitation.\(^7\) The precipitation methods most frequently employed use heat, alcohol, HCl–acetone, trichloroacetic acid (TCA), perchloric acid (PCA) and sulfosalicylic acid. Since various concentrations of certain reagents precipitate different percentages of protein, specification of the type and concentration of the precipitating agents used is required.\(^14\) The nature of the NPN fraction in cows’ milk and methods for determining the NPN constituents were described by Wolfschoon-Pombo et al.\(^15,16\)

Possible interfering compounds in protein determination methods are carbohydrates, salts, lipids, and detergents. Also, the amino acid composition of a particular protein can influence the response of proteins, e.g. color development in a dye-binding assay. Therefore, the calibration of the assay using an appropriate protein mixture is recommended in order to obtain accurate measurements. In the following section, specific attention will be given to three methods: Kjeldahl, IR spectroscopy and dye binding. Advantages and disadvantages of these three methods are presented in Table 1.

2.1 Kjeldahl Method

Although it has been subject to modification over the years, the basic Kjeldahl procedure is still the most universal technique available for the determination of organic N, and it is therefore internationally recognized for official and statutory purposes. A great advantage of the Kjeldahl procedure over other protein determination methods is the possibility of determining insoluble proteins. The Kjeldahl method is applied as a reference method to calibrate direct methods of protein determination.

The Kjeldahl procedure involves two steps: digestion of the sample by heating with concentrated sulfuric acid and the determination of the ammonia released. Concentrated sulfuric acid is an effective dehydrating agent. At a given critical temperature, the elements of water from oxygen-containing organic matter are extracted and carbon is liberated. At the decomposition temperature sulfuric acid also acts as an oxidant and oxidizes the liberated carbon to carbon dioxide. This causes conversion of organic N into ammonia which is retained in solution as ammonium sulfate. In the first stage, the transformation of N into ammonia is rapid, but it subsequently becomes increasingly slower. To guarantee the complete decomposition of more resistant intermediates, an additional period of boiling (after-boil) after the digest is recommended.

The decomposition step can be accelerated and completed by adding salts, oxidants, or reductants and using catalysts. When using these accelerating agents, a process time of 10–45 min for the total digestion step has been reported. The addition of salts increases the boiling-point and shortens the decomposition time for organic compounds. The salt generally used is K₂SO₄. The addition of oxidants significantly accelerates digestion and decreases foaming. The oxidants mainly applied are hydrogen peroxide, PCA, persulfates, and chromic acid. To determine the total N content in plant materials containing nitrate, the addition of reductants is necessary for the conversion of the nitrate N into ammonium ions. Reduction is also necessary in the determination of the N of azo, nitro, oxime, isoxazol, hydrazine, and hydrazone groups. Metallic zinc or copper, titanous chloride, sodium dithionite, benzoic acid, or phenol can be used. Salicylic acid and metallic zinc are recommended for the complex and to release the ammonia into solution. Copper is the most widely used catalyst nowadays. Additional information on the use of salts or oxidants in the digestion process was given by Gaspar and Lakin reported some guidelines for the selection of a suitable catalyst.

The ammonia formed in the digest can be determined by titrimetry, spectroscopy, or potentiometry. In the titrimetric method, the digest is distilled or steam distilled in the presence of alkali to release the ammonia. By direct distillation with moderate heating, the ammonia can be quantitatively distilled off in <20 min, depending on the size of the apparatus. A steam-distillation apparatus needs a maximum of 10 min for the quantitative distillation of the ammonia. In a frequently used procedure, the liberated ammonia is adsorbed in an excess of boric acid solution and can then be titrated with standard acid (HCl, H₂SO₄) in the presence of an indicator. Spectroscopic methods are mainly used for the direct determination of the ammonia in the decomposition solution, making unnecessary the time-consuming distillation and titration steps. In addition, they are more advantageous than titration for the determination of microquantities (0.1–1.5 μg mL⁻¹). Color reactions of ammonia with Nessler reagent (HgI₂⁻), indophenol, and ninhydrin can be used for spectrometric determination. However, the catalysts used in the Kjeldahl method can disturb the color reactions of ammonia.

In the potentiometric determination, the distillation–titration steps are replaced by the application of an ammonia-specific electrode (ammonia gas-sensing probe), which shortens the digest analysis time to 5–10 min. Ammonia gas-sensing probes measure the partial pressure of gases in solution. Copper and mercury in digestion catalysts may interfere by complexing ammonia. This may be prevented by the addition of the disodium salt of ethylenediaminetetraacetic acid (EDTA) or sodium iodide, respectively.

On a macroscale, modern types of Kjeldahl apparatus allow the analysis of N in the range 0.2–160 mg per sample. The application of the Kjeldahl method can be manual, or semi- or fully automated. Fully unattended operation allows the analysis of 60 samples in up to 4 h. The Berthelot procedure is particularly applicable to micro-Kjeldahl analysis. This procedure involves a wet digestion similar to that in the Kjeldahl method, after which the ammonia formed is determined by colorimetry. Nitrogen concentrations in the range 0.3–1.3 μg N mL⁻¹ for the sample digest could be determined. Automation of the Berthelot reaction allowed the determination of ammonia at the rate of 40 samples per hour. Different procedures based on the Kjeldahl method have been studied and optimized for meat, milk, and cereals.
2.2 Infrared Spectroscopy

Most organic products have an absorption in the IR region. Absorption of radiation at IR frequencies by molecules is the result of transitions between vibrational energy levels. Atoms vibrate in complicated patterns affected by atomic masses and strength of atomic bonds. Functional groups, such as O–H, N–H, and C–H bonds, will absorb various IR frequencies. The pattern of the various IR frequencies absorbed provides information about the sample composition. The degree of IR absorbance by functional groups at specific wavelengths can be correlated with the concentration of constituent compounds of the sample. The near-infrared (NIR) spectral region is the part of the electromagnetic spectrum between 800 and 2500 nm. It is the intermediate region between the VIS part of the electromagnetic spectrum (400–750 nm) and the IR spectrum (2500–30000 nm). The higher energy content of NIR compared with IR radiation is suitable to induce transitions to higher vibrational levels and to cover absorption bands related to combined interactive vibrations. NIR has important advantages over IR spectroscopy for quantitative analysis. Since the absorbivities are much lower for overtone and combination bands compared with the fundamental bands, moderately concentrated samples and pathlengths comparable to those usually applied in the VIS or UV region may be used, thus permitting the analysis of intact samples such as protein fibers.\(^9\)

In the quality control of milk, IR spectroscopy is routinely used to determine the protein content by measuring the absorption band at a wavelength of 1548 cm\(^{-1}\), which corresponds to the absorption maximum of the peptide bond. The quantification of lactose (1042 cm\(^{-1}\)) and fat (1745 cm\(^{-1}\)) can be applied simultaneously. The two main technological problems are the high water content of milk and the heterogenity of the fat globules.\(^8\) Water absorbs a large quantity of energy between 1000 and 5000 cm\(^{-1}\) which disturbs the protein absorption bands in the IR spectrum. To neutralize this problem, a double-beam spectrophotometer with water in the reference cell can be used. Fat globules in milk display a similar diameter to the wavelength of the light beam, which causes light diffusion and diminuation of the absorption peak. To reduce these phenomena, fat globules have to be homogenized (to <2 µm) and absorption bands have to be selected in the region of longer wavelengths.

In NIR spectroscopy, a spectrum may be collected from a sample in two ways: by transmission through the sample and by reflection from the sample. Transmission techniques are suitable for a wider range of samples, from clear films and liquids through highly scattering solutions, pastes, slurries, and suspensions. The reflectance mode is best suited to opaque powders and to solids moving in a dense phase. NIR technology offers the facility for rapid (the analysis time is <1 min) and accurate protein testing and the technique is used on a routine basis. In addition to the fact that NIR reflectance makes it possible to determine insoluble proteins and analyze almost intact food samples, another advantage over other methods of protein determination is the simultaneous detection of other constituents such as moisture and lipids.\(^{9,26}\)

NIR reflectance analysis had a considerable impact on the cereal industry. To avoid interferences due to starch, oil, and water, the optimum wavelength for the quantification of the protein constituents is 2180 nm, which is the position of a band assigned to a combination of twice amide I plus amide III.\(^9\) Variations in particle size between different samples and variations in the levels of starch, oil, and water cause larger changes in NIR reflectance at 2180 nm than changes in protein content. A correction for these effects can be made by using an adapted calibration procedure where specific absorption bands for protein, starch, oil, and water are taken into account. For all chemical methods of protein determination, the sample of grain must be ground prior to analysis to render the grain to a meal having a similar particle size distribution to that of flour.\(^9\) The standardization of the grinding method for NIR reflectance analysis is more important than that for chemical methods because the reflectance characteristics are strongly influenced by particle size. For ground wheat, some errors in predicting protein in flour with NIR reflectance result from such factors as particle size differences, moisture losses during grinding, and sample homogeneity. A study\(^{27}\) claimed that under normal practical conditions, the NIR analysis of whole wheat samples may prove to be the more accurate procedure because these errors with ground wheat are known to be even larger under practical field conditions than under careful research conditions.

On-line NIR systems to evaluate the quality of meat are already on the market to assay water, proteins, lipids, and collagen. A difficulty is found with products such as ham and other fine meat products; while the absorption bands in the NIR method are mainly influenced by the protein fraction, the Kjeldahl procedure, as a reference method, determines the total N content and thus also the nitrates.\(^{28,29}\) A further improvement of the NIR technique is obtained by using the whole spectrum or large parts of it, rather than one or a few wavelengths. Quantification is then achieved by chemometrics.\(^{30}\)

2.3 Dye Binding

Under appropriate conditions (pH and ionic strength of the medium), the acidic and basic groups of proteins
interact with dissociated groups of organic dyes (e.g., the acid radicals of sulfonic acids) to form colored precipitates. Examples of colorants used are Amido Black 10-B, Acid Orange 12 and Coomassie Brilliant Blue (CBB).

In indirect protein determination methods utilizing dye binding, the excess of dye was found to be indirectly proportional to the amount of protein present. The principle of those methods was to remove the unsoluble protein–dye complex by filtration or centrifugation and to measure by spectroscopy the excess of dye in solution. An indirect dye-binding method was employed (7) to determine the basic and acidic groups, and their ratios, in the proteins of wheat flour fractions. Dye binding may vary with the amino acid composition of the particular protein, e.g. primarily basic (especially arginine) residues, rendering them partially or completely unavailable to react with the dye. (35) Instruments for manual and semi- and automatic determination of protein by a dye-binding method are on the market for cereals (36) and dairy products (37,38).

3 DETERMINATION OF SPECIFIC NITROGEN COMPOUNDS

Various instrumental techniques are available to determine specific N compounds in food such as amino acids, peptides, and proteins. Separation of the individual N compounds is based on specific properties, mainly the charge-to-mass ratio and structural properties. These specific characteristics are exploited in techniques such as gas chromatography (GC), high-performance liquid chromatography (HPLC), electrophoresis, CE, and immunological determinations. In the following sections each of these techniques will be briefly discussed with emphasis on their applicability for the separation and/or determination of food proteins, peptides, and amino acids. Examples of recent applications and some general guidelines are given. The separation and analyses of individual N compounds is for quantification purposes in addition to identification of particular proteins or protein fractions. For instance, detection of the adulteration of high-quality dairy products by addition of components with lower quality or which are cheaper than the original product is becoming more and more important. (39)

3.1 Gas Chromatography

GC is based on differences in the affinities of the compounds to be separated for the mobile phase, usually a carrier gas such as He or N2, and the stationary phase. A prerequisite for the application of GC for separations of compounds in general is that these compounds must be volatile or can be converted into volatile derivatives. Taking into account the relatively high MW of peptides and proteins and their characteristic structure and conformation, GC is only useful for the separation of amino acids. A serious drawback of GC separations of amino acids, compared with other analytical methods, is the complicated and not automatable derivatization. (40) Analysis of amino acids by GC after acid hydrolysis of the proteins has been applied to canned foods. Amino
acids were determined as heptafluorobutyryl isobutyl ester derivatives after separation on a packed column with methylsilyl or an open column with dimethylsilyl as mobile phase. Detection was carried out with a thermionic nitrogen–phosphorus detector. A rapid screening method for free amino acids consists of picric acid treatment and solvent washing of a water extract of the sample for the isolation of free amino acids. The amino acids are derivatized into zwitterionic S-amino acids and subsequently silylated to stable tert-butyldimethylsilyl derivatives. Detection was carried out with mass spectrometry.

The GC analysis of amino acids is a very sensitive method. However, the intrinsic disadvantages have led to GC being dominated by HPLC as the prefered method for amino acid analysis.

### 3.2 High-performance Liquid Chromatography

The principle of HPLC is very similar to that of GC but in the case of HPLC the mobile phase is a solvent or a mixture of solvents. Based on the separation mechanism and stationary phase, different HPLC modes can be distinguished. The different HPLC modes and some properties are listed in Table 2. A review of HPLC techniques for the separation of food proteins and applications was given by Dierckx and Huyghebaert.

HPLC is an excellent technique for the separation of proteins and also peptides and amino acids. However, depending on the sample type, HPLC mode, and analytes to be detected, thorough sample preparation and cleanup procedure may be required. This is especially the case for amino acid analysis, which is one of the most difficult and complicated analyses to be carried out in food analysis procedures. Sample preparation can include removal of interfering components such as lipids and nucleic acids and solubilization of the analytes. Separation of the different classes of proteins in a sample can be achieved by selective precipitation. This includes the use of salts, organic solvents, or heat. Some examples of sample pretreatments are given in Table 4.

Separation conditions and equipment requirements depend very much on the choice of the HPLC mode. From this point of view, SEHPLC can be considered as the simplest method to perform since no gradient elution, in which the composition of the mobile phase changes during elution, is used. A typical mobile phase for SEHPLC consists of a buffer at near neutral pH, e.g. phosphate or Tris buffer, with a low concentration of salt in order to supress ionic interactions of proteins with the stationary phase. The other modes of HPLC are more complicated to perform since elution of analytes is based on the competition of analyte molecules and the (changing) mobile phase for the stationary phase. Typical mobile phases for RPHPLC of proteins, peptides, and amino acids are aqueous mixtures of acetonitrile or propanol in the presence of small amounts (~0.1%) of, e.g. TFA or heptafluorobutyric acid. Increasing the hydrophobicity of the mobile phase by increasing the ratio of organic solvent to water in the mobile phase causes elution of the proteins, based on their hydrophobicity. In the case of HIHPLC, elution is obtained by changes in the ionic strength of the mobile phase. This principle is also used in IEHPLC, in addition to changes in the pH of the elution buffer. Since good control of the gradient conditions is necessary to obtain good reproducibility, perfect control of the composition of the mobile phase is required. This is achieved by using two solutions which are mixed in a certain, changing ratio throughout the separation and which requires high-quality equipment.

The method of preference for the determination of amino acids is HPLC. However, the analytical procedure is very much dependent on the purpose of the analysis: determination of free amino acids or the total amino acid profile of a food product, and quantification of amino acids or identification of the presence of any particular amino acid. Determination of free amino acids is far simpler than the determination of the total amino acid profile since the latter requires hydrolysis of the protein molecules into their constituent monomers, preferably without destruction or transformation of any particular amino acid and with the total hydrolysis and release of the hydrolyzed amino acids. Free amino acid analysis usually includes two steps: rendering the material extractable in the case of solid foods, e.g. by homogenization or grinding, and solubilization of the free amino acids. This is achieved by stirring with a suitable solvent, e.g. dilute HCl. Precautions have to be taken because some amino acids might be tightly bound to proteins or may be labile to acidic conditions. Total hydrolysis of proteins for determination of the total amino acid profile is generally performed by acid hydrolysis of the peptide bond (6M HCl, 105–120°C for 18–24h under N2). However, this method has some drawbacks, especially when critical parameters such as purity of acid, acid-to-protein ratio, temperature, time, and O2 are not under control. Possible problems are the degradation of Trp, oxidation of Cys, dehydration of Ser and Thr, and conversion of Gln and Asn into their acid forms. This has led to the development of other methods such as the use of other acids (methanesulfonic acid, performic acid), alkaline (4.2 M NaOH, 110°C for 22h) or enzymatic hydrolysis, or the incorporation of protecting agents [thioglycolic acid, tryptamine, or β-mercaptoprotoethanol (ME)]. A further complication is the fact that most amino acids do not have useful UV or

fluorescence absorbances, requiring derivatization of amino acids to permit detection by conventional means (UV or fluorescence detection). Derivative formation can be done pre- or postcolumn, primarily depending on the HPLC mode used for separation. Precolumn derivatization is commonly used with RPHPLC since it renders the amino acids more hydrophobic. A major advantage of this procedure is an unlimited reaction time, allowing the tailoring of the analysis to a particular matrix. An overview of possible precolumn derivatization techniques with some properties is given in Table 3. Postcolumn derivatizations for the analysis of amino acids are almost exclusively used in combination with IEHPLC (cation exchange) with ninhydrin or \( \alpha \)-phthalaldehyde in the presence of a thiol as derivatizing agents. Various problems are connected with this method: the postseparation volume is increased and a postcolumn reaction vessel is required, which results in loss of resolution. Underivatized amino acid separation limits flexibility and the derivatization reaction needs to be very fast. Both, IEHPLC and RPHPLC are currently in use for amino acid analysis and a comparison between the two methods was made by Bütkofer et al. Various automated HPLC systems for the analysis of amino acids are available, e.g. the Pico-Tag system from Waters (Millipore, Bedford, MA, USA).

Peptides can be analyzed by RPHPLC in much the same way as proteins. However, some problems may occur, e.g. with UV detection, where other food components may interfere at the low wavelengths used for peptides, during SEHPLC, where peptides all elute in the void fraction, or separation of small hydrophilic peptides (di- and tripeptides) which are normally not resolved during a classical RPHPLC separation. Selective and sensitive methods have been developed for the detection of peptides, usually based on the same principles as those used for the detection of amino acids including both precolumn and postcolumn derivatizations.

A good overview of the possibilities of RPHPLC for peptide separations and evaluation of various detection techniques was given by Herraiz.

Analysis of proteins by HPLC has become a widely applied method in many laboratories since the introduction of columns with suitable packings for protein analysis by Waters (Millipore) in the late 1970s. Nevertheless, routine applications are mainly limited to milk and cereal proteins, as can be derived from the number of publications in this field. Analysis of milk proteins includes quantification of caseins and whey proteins, identification of milk from different species, and postcolumn derivatizations. Analysis of milk proteins includes quantification of caseins and whey proteins, identification of milk from different species, and postcolumn derivatizations. Analysis of milk proteins includes quantification of caseins and whey proteins, identification of milk from different species, and postcolumn derivatizations.

Applications to wheat proteins are found in the differentiation between various cultivars and species identification in wheat, adulteration of durum wheat with common wheat, and relating protein composition with dough-making properties and bread quality. Furthermore, HPLC has proven to be useful for the analysis of egg, meat, proteins, fish species identification, soybean hydrolysates, peanut proteins, the analysis of mixed protein systems, and species identification in meat samples. In order to give an overview of the possibilities of HPLC for the analysis of proteins in foods, a summary of some procedures is outlined in Table 4.

3.3 Electrophoresis

Electrophoresis refers to the movement of charged particles in an external electrical field. The mobility of a charged molecule is dependent on its charge-to-size ratio, the size being determined by MW, the three-dimensional structure, and the degree of solvation. Nowadays, conventional electrophoresis is almost exclusively performed in slab gel systems. The gel medium stabilizes the buffer medium against convectional flow and improves the separations by its sieving action. The sample mixture is brought on to the gel and a voltage difference is applied over the gel. Proteins and peptides, having a specific charge at a certain pH value, will migrate towards the electrode of the opposite sign. The net charge, however, is conformation dependent, so protein electrophoresis is strongly influenced by pH, temperature, and ionic strength. In addition to charge, the electrophoretic mobility is also influenced by macromolecular size and shape of the proteins and peptides, and thus the pore-size distribution of the gel matrix.

A frequently used gel medium is polyacrylamide in a method known as polyacrylamide gel electrophoresis (PAGE). Several samples can be analyzed at the same time and therefore under the same conditions of electrophoresis. In most commercially available systems, the gel is mounted on a cooling plate, so the heat produced during the electrophoresis is removed, resulting in a superior resolving power and greater flexibility. Gels can be either homogeneous (fixed pore size) or gradient (increasing pore size) type. Different electrophoretic modes can be distinguished:

- **SDS/PAGE**: SDS is an anionic detergent. When proteins are dissolved in SDS solution they lose their individual charges and all proteins acquire the same negative surface charge density, giving a separation based on differences in molecular size. The MW of proteins can be determined by measuring their electrophoretic mobility in SDS-containing polyacrylamide gels.

- **Urea or native PAGE**: proteins are separated based on their charge-to-mass ratio.

- **IEF**: a stable pH gradient is created between the anode and the cathode by the use of ampholytes. The proteins migrate towards the electrode of opposite charge and focus at those positions on the pH gradient where they have no net charge, also called the isoelectric point (IEP).

Classical slab electrophoresis is still performed mainly manually, although semiautomated separation, staining, and scanning units exist, and requires highly skilled personnel in the gel pouring, sampling, separation, and staining/destaining procedures. A wide variety of premade gels, with various degrees of cross-linking and with fixed gradients, are commercially available. Using these gels has the advantage of a higher reproducibility and a shorter analysis time. Furthermore, it reduces the risk of exposure of researchers to the neurotoxic acrylamide. A more comprehensive description of gel electrophoresis was given by Creighton.

After separation, proteins and peptides have to be fixed on the gel and have to be visualized. Fixation agents such as 20% (w/v) TCA or methanolic solutions of acetic acid can be used. After the separation process, proteins and peptides are precipitated and immobilized by these agents. Peptides, however, need to have a certain size, i.e., ~10kDa, in order to be separated and fixed on the gel. Interfering nonprotein components are removed prior to staining. Since proteins and peptides lack sufficiently high UV absorption or fluorescence, the use of specific dyes is necessary. Protein staining is usually achieved by the use of CBB G 250 or R 250, which benefits from its speed of operation and relatively low background staining but which is rather insensitive (0.5 μg protein cm⁻² gel). Furthermore, CBB does not obey Beer’s law at high concentrations, which can interfere during the spectrophotometric scanning of the gels and can give erroneous results in quantification procedures based on the density profiles. Silver staining techniques may increase the sensitivity by a factor of 20–200 but they are more expensive and time-consuming than CBB staining. Since the number of samples per gel is limited and differences in the degree of staining between different protein components exist, electrophoresis can only be used as a qualitative or semiquantitative analytical tool for N compounds in foods.

Sample preparation in the case of conventional electrophoresis is usually very simple and often consists of mixing or grinding the product to be analyzed with a suitable buffer, containing urea (6–8 M) and ME (0.1–5%) or DTT to dissociate protein complexes. A prefractionation of proteins can be achieved by selective precipitation at a certain pH. In the case of fat-containing products, e.g., cheeses or milk, the fat can be removed by centrifugation, with or without the addition of organic solvents. For SDS/PAGE, boiling proteins at slightly alkaline pH (~8) in the presence of SDS (~0.1%) and ME is usually included in the sample preparation. Disulfide linkages are reduced and the dissociated chains bind SDS and adopt a random coil configuration. The denaturating capacity of SDS is sometimes unfavorable since it changes the naturally occurring state of proteins. If this native stage is required, e.g., for detection of electrophoretically separated proteins by immunological
Electrophoresis can also be performed in free solution if the heat produced can be dissipated efficiently. Tubes with small inner diameter have a high surface-to-volume ratio, which facilitates heat dissipation. In the early 1980s, the use of capillaries for electrophoretic separations of analytes was demonstrated and ever since CE has developed into a powerful separation technique. It is ideal for handling small sample amounts and is similar to HPLC in its ease of operation, speed, on-line detection, and full automation capabilities. The high efficiency of CE is due to its characteristic flat flow profile, which allows for narrower peaks and therefore a higher resolution than conventional HPLC. Furthermore, CE requires no staining and destaining steps, and shows real time separation. However, the use of small sample amounts often means a high concentration limit of detection and considerable effort is devoted to improving the concentration sensitivity of the technique. Different detection methods are being used with CE: UV/VIS absorbance, fluorescence, derivatization, mass spectrometry, and indirect, laser-based, or electrochemical detection. However, only UV/VIS and to a lesser extent derivatization are of practical importance for proteins. CE is almost exclusively performed in fused-silica tubing which exhibits good thermal properties, is transparent to UV/VIS light and can be made with an inner diameter of less than 100m. Typical for fused-silica capillaries is that, for a wide range of pH values, the inner wall is negatively charged owing to ionization of the silanol groups. Consequently, it attracts cationic counterions from the bulk solution with the formation of an electric double layer at the silica—solution interface. When an electric field is applied, the hydrated cationic species will migrate towards the cathode causing bulk solutes to move in the same direction. This phenomenon is called electroosmotic flow (EOF) and is often greater than the electrophoretic mobility of any molecule present in solution. Different modes of operation and detection modes have been developed.

For FSCE, the capillary is filled with electrolyte and the ends are immersed in vials containing electrolyte or sample solution. Because of differences in the intrinsic electrophoretic mobilities and the phenomenon of EOF, both cations and anions can be separated in a single run. Neutral molecules, however, will not be resolved since they will travel in one zone with a velocity equal to that of the EOF. Although proteins can be separated by simple FSCE, precautions have to be taken since proteins tend to adsorb to the capillary wall through a variety of mechanisms causing broadening and/or tailing of peaks and sometimes poor quantification. This can be (partially) overcome by using a high- or low-pH buffer, a high-ionic-strength buffer, coated capillaries, or buffer additives. Since protein adsorption can influence the migration time reproducibility, rinsing the capillary between injections, e.g. with water, NaOH, air, N2, and buffer for a short period of time, is often necessary. Which approach is used depends very much on the proteins to be separated. Buffer additives are exploited to separate neutral molecules and to improve the separation of proteins and peptides by the inclusion of micelle-forming detergents or surfactants in the electrophoretic medium; this is called micellar electrokinetic chromatography (MEKC). Surfaceants exhibit both hydrophobic and hydrophilic character and, in an aqueous environment, self-aggregate into micelles if the surfactant concentration exceeds the critical micelle concentration (cmc). During an MEKC separation, proteins associate with micelles through hydrophobic, hydrophilic, and electrostatic mechanisms. Many successful CE separations of proteins have been facilitated by the presence of both charged, e.g. SDS, and neutral or zwitterionic surfactants. In addition to protein adsorption on the inner wall, the introduction of a well-defined sample volume can be a problem. Samples can be introduced into the column hydrodynamically or by electrokinetic introduction. The former can be achieved by applying a positive pressure to the inlet of the capillary or negative pressure at the outlet, for a specified period of time. Electrokinetic sample introduction is based on the transport of an aliquot of the sample in the column by the EOF. Parameters to be controlled are time, temperature, and liquid levels at inlet and outlet reservoirs. It seems that hydrodynamic injection is more reproducible than electrokinetic injection; however, the use of internal standards is often required for either introduction technique. This approach permits corrections for the variations in introduced volume and for losses during sample cleanup. A further complication is that analytes do not pass the detector all at the same speed since differences in migration velocities are the basis for separation. Zones traveling past the detector at high velocity will produce sharper peaks with smaller area than to slow-traveling zones, even though they might have the same concentration and extinction coefficients. Since this is a systematic bias, peaks can be corrected for differential mobilities by normalization with their retention time. Although sharp peaks can be obtained which facilitate integration, the small sample volume introduced together with the short optical pathlength often result in high concentration limits for detection. Different attempts are being made to overcome this major drawback, including modifying capillary geometries, preconcentration of analytes, e.g. by stacking, indirect detection methods and the development of alternative detection modes.
Since conventional electrophoresis is generally accepted as being a qualitative rather than a quantitative analytical tool, the quantification of proteins and peptides is mostly limited to CE. CE has the advantage over HPLC that it has high theoretical plate numbers (200,000–500,000). Although results are still less repeatable for complex mixtures.

A good example of the resolving power of electrophoresis is the separation of wheat proteins from different cultivars where electrophoretic techniques permit differentiation between closely related wheat cultivars. A main problem in cultivar identification by using conventional electrophoresis arises from experimental variations such as partial deformations on the whole gel and partial distortion of single bands. This led to a lot of effort being put into the development of HPLC methods but not all separations were performed as well as with electrophoresis. A good separation of individual milk proteins either in milk or dairy products can be achieved by conventional electrophoresis methods such as SDS/PAGE and IEF. Separation of genetic variants is usually carried out by IEF or urea–PAGE since the genetic variants have comparable MWs but slightly different IEPs. Since its introduction, CE has become a popular technique to analyze milk proteins. Separation of the genetic variants of milk proteins is strongly dependent on buffer pH and ionic strength, and analysis times comparable to those in HPLC are often necessary for a complete resolution of caseins and whey proteins in a single run. Further optimizations have been done and variants differing in only a single amino acid could be separated as long as this substitution involved a change in the net charge at pH 3.0. Quantification of the major whey proteins has been continuously improved during the past 5 years and current research on CE of milk proteins is mainly directed towards the optimization of the separation conditions, e.g. the inclusion of surfactants in the separation buffer, in order to reduce the analysis time further and to have a good quantification of all milk proteins in a single run. The possibilities of conventional electrophoresis for identification purposes were very well realized during the early days of electrophoresis. Since the early research in the 1970s and 1980s, much effort has been directed to refining the procedures, to lowering the detection limits, and to reducing the time required for an analysis. Detection of adulterations by electrophoretic techniques have been reported for both raw and cooked meat and meat products. Detection of the incorporation of low-quality meat such as mechanically recovered meat (MMR) in all types of meat products, including cooked meat products, has also been reported, with detection limits as low as 5–10%.

The identity of raw and cooked fish is determined with differences between species being much greater with IEF than with SDS/PAGE. Semiquantitative results with SDS/PAGE can be obtained with the inclusion of an internal standard, e.g. BSA for the determination of beef myofibrillar proteins or the peptide Lys-Trp-Lys. Adulteration of high-quality products with lower quality or lower priced ingredients is also of importance in the dairy industry. Sheep, goat and buffalo milk are all used to make cheese and detection of the use of mixtures of milks from different species is of great economic importance. Differences in the electrophoretic pattern of the milk of the various species can be found in the casein fraction and whey proteins. Changes in the protein fraction during processing, e.g. protein hydrolysis during the ripening of cheese or aging of dry cured ham, are successfully studied by both conventional electrophoresis and CE. The importance of different factors during processing has also been evaluated by electrophoresis. Protein denaturation can be evaluated by electrophoresis, e.g. protein denaturation by heat or high pressure. Applications of electrophoresis to proteins other than milk, meat, and cereal proteins are much less numerous but have been reported for, e.g. garlic, kiwifruit, peanut and fermented beverages. Examples of analysis conditions for electrophoresis are given in Table 4.

### 3.4 Immunological Detection Methods for Food Proteins

Several protein detection methods based on immunology have been described in review articles. ELISA seems particularly suitable for the routine analysis of proteins in food matrices. These immunosassays are based on the specific interaction between an antigen (in this case the food protein) and an antibody which reacts specifically with the antigen. The antigen–antibody interaction can be detected by the use of enzymes, e.g. alkaline phosphatase and peroxidase, which catalyze the transformation of a colorless substrate into a colored product to a degree which is related to the amount of antigen present. The method is particularly suitable for application in multiwell plates, is relatively fast in operation, and can be applied by non-specialized laboratory personnel. A significant amount of experimental research has now been performed to evaluate the suitability of ELISA in the detection and quantification of protein compounds in food matrices. Applications are found in the detection of allergenic compounds in foods, e.g. peanut proteins, gluten and rice bran protein, and in tracing the adulteration of foods, e.g. detection of milk proteins in goats’ and ewes’
milk and cheese,\textsuperscript{162,163} and detection of soy proteins in milk\textsuperscript{170} and meat products.\textsuperscript{169,171}

Different variants of ELISA techniques have been applied to determine proteins in food products. Common are heterogeneous assays where the enzyme activity is not affected by the antigen–antibody interaction and where a separation between bound and unbound materials occurs.\textsuperscript{172} Several authors have used indirect competitive ELISA in food protein analysis.\textsuperscript{162–164,167,173} The antigen is immobilized to a solid support, after which the primary antibody and the sample (containing the antigen) is added to the solid phase. The primary antibody binds to the antigen present in the sample which prevents the antibody from binding to the immobilized antigen. After removal of unbound material, the antibody attached to the solid phase is determined by addition of an enzyme-labeled secondary antibody, which specifically interacts with the remaining primary antibody, and an enzyme substrate.\textsuperscript{11,172} Methods based on this principle were used to detect the presence of cows’ milk and casein in goats’ and ewes’ cheese.\textsuperscript{162} to evaluate the residual antigenicity of whey proteins after hydrolysis with endo- and exopeptidases\textsuperscript{167} (Table 4).

Proteins in foods have also been determined by double antibody sandwich ELISA.\textsuperscript{165} Antibodies raised against the protein are coated on a solid support, after which the sample containing the antigen is added. Unbound material is removed by washing and bound antigen detected by a second antibody labeled with an enzyme.\textsuperscript{172} The method was used by Helle et al.\textsuperscript{165} to quantify peanut proteins in extracts from different foods with a concentration range from 40 µg peanut protein mL\textsuperscript{−1} up to 2.0 mg mL\textsuperscript{−1}. The secondary antibody was labeled with biotin, which was coupled in a separate step to peroxidase by streptavidin.

A critical step in the development of immunoassays is the formation of antibodies which are highly specific for the component of interest. Both monoclonal\textsuperscript{165,170} and polyclonal\textsuperscript{11,163,165,166,173} antibodies have been developed for analysis of food proteins. Cross-reactivity with closely related antigens may reduce the specificity of the assay, e.g., indirect competitive ELISA developed by Richter et al.\textsuperscript{162} for detection of bovine casein in ewes’ and goats’ milk cheese shows cross-reactivity with closely related buffalo \(\gamma\)-caseins. Nevertheless, by using immunoabsorption chromatography, they were able to remove all antibodies cross-reacting with ewes’ and goats’ milk protein. The specificity of the antibody can also be influenced by the three-dimensional structure of the protein–antigen, e.g. the immunoreactivity of food proteins can be altered due to denaturation during manufacturing. Beer et al.\textsuperscript{163} succeeded in developing an ELISA to detect both native and heat-denatured bovine \(\beta\)-lactoglobulin in ewes’ and goats’ milk cheese. Since the degree of denaturation of bovine whey proteins used in adulterated cheese is not exactly known, it was chosen to use an extra standardized heat treatment (30 min at 90°C) during the sample preparation to reduce the influence of individual thermal history of the samples. The method was found suitable to detect adulteration of ewes’ and goats’ milk cheese with ultra high temperature (UHT) and pasteurized cows’ milk. In the case of soy proteins, an antiserum was produced by using a standardized denaturation and renaturation procedure.\textsuperscript{171} Immunoreactivity was found against glycinin, which was denatured by boiling for 30 min in 10 M urea. Nevertheless, nonspecific interactions occurred with urea-denatured casein. Meisel\textsuperscript{170} developed antibodies with high specificity but still suitable for detection of glycinin A subjected to different food processing conditions, by denaturing the proteins at 100°C for 5 min in the presence of SDS and DTT. At a concentration of 0.05%, the SDS was able to reduce nonspecific interactions of the antibody with fava bean and pea proteins. The effect may be due to blocking by SDS of binding sides involved in nonspecific antigen–antibody interactions. Hydrolysis of a whey protein concentrate (WPC) with corolase 7092 (a technical mixture of endo- and exopeptidases derived from Aspergillus sp.) resulted in a decrease in the antigenicity of BSA and Ig up to a degree of hydrolysis (DH) of 25%, after which a significant increase in antigenicity was found. It was suggested that prolonged enzyme action led to the exposure of more antigenic sides due to protein unfolding.\textsuperscript{167} The binding ability of proteins for antibodies can also be altered by the degree of lipophilization. Akita and Nakai\textsuperscript{164} found that during indirect competitive ELISA the interaction with immunoglobulin G (IgG) increased at low and medium levels of fatty acid incorporation (0.3 mol of stearic acid per mole of lysine), while the binding activity decreased when more fatty acids were attached to the protein (>13 mol stearic acid per mole of lysine). The result was attributed to differences in the degree of unfolding in function of lipophilization, which can alter the exposure of antigenic sides during ELISA.\textsuperscript{164} In addition to the development of highly specific antibodies, the degree of nonspecific binding in ELISA can also be reduced by treatment of the solid support with a suitable blocking agent.\textsuperscript{171} After coating the plates with antigens or antibodies, unoccupied sides remain on the support where nonspecific binding can take place. Blocking agents frequently used are gelatin,\textsuperscript{11,163,167,170} BSA,\textsuperscript{165,171} and ovalbumin.\textsuperscript{168}

Heddleson et al.\textsuperscript{177} indicated that peptides with MW below 2500 Da are not immunogenic without modification, whereas proteins with MW below 10 kDa show only a weak immunogenic response. Rats injected with caseinphosphopeptides derived from tryptic hydrolysis of \(\beta\)-casein did not produce IgG antibodies that
cross-reacted with β-casein or skim-milk proteins.\textsuperscript{177} Ena et al.\textsuperscript{167} demonstrated that permeates of WPC hydrolyzates obtained by ultrafiltration and showing the same DH or a similar MW distribution gave differences in antigenicity of BSA and IgG compared with α-lactalbumin and β-lactoglobulin. This led to the conclusion that the residual antigenicity of whey proteins after hydrolysis is determined by the specificity of the enzymes used rather than by the DH or the MW distribution of the protein hydrolyzates. Also for chickpea proteins a dominating influence of enzyme activity was found. The antigenicity of native chickpea proteins during indirect competitive ELISA was reduced by 58% after hydrolysis with α-chymotrypsin compared with 45% for bromelain.\textsuperscript{178}

4 CERTIFIED REFERENCE MATERIALS

Certified reference materials (CRMs) are an important tool in the validation of methods used to analyze N-containing compounds in foods. These materials are accompanied by a certificate, giving certified values for the amount of N present in the food matrix with an indication of the degree of uncertainty at a stated level of confidence (usually 95% confidence interval).\textsuperscript{179} Several CRMs to analyze N-containing components in foods are available at the Institute for Reference Materials and Measurements (IRMM) of the European Commission. Kjeldahl N has been determined in rye flour (CRM 381), wheat flour (CRM 382 and CRM 563), beans (CRM 383), and pork muscle (CRM 384).

CRMs are prepared in the form of dry and homogeneous powders with good stability characteristics. Skim-milk powder (CRM 063R) has been prepared by homogenizing spray-dried skim-milk powder under dry argon in a mixing drum for a period of 14 days.\textsuperscript{180} Lyophilized pork muscle (CRM 384) is derived from ca. 200 kg of muscle separated from connective tissue and visible fat in lean pigs. The muscle is minced and blended with subeutaneous pork fat and antioxidant (α-tocopherol), frozen at −20°C, and lyophilized.\textsuperscript{181} Powders are packaged under dry N₂ and stored at 4°C. Samples of the powdered reference materials are analyzed by different laboratories with a high level of expertise, where each laboratory is permitted to use its own well-established method of analysis. Although for the determination of Kjeldahl-N in pork muscle a wide range of catalysts (CuSO₄, HgO, Se, TiO₂), reaction conditions (application of different digestion times and amounts of H₂SO₄, presence or absence of H₂O₂), and equipment (automated versus manual titration) have been used, low levels of uncertainty were obtained, i.e. 13.7 ± 0.2 g Kjeldahl-N per 100 g dry matter for pork muscle.\textsuperscript{181} Results are expressed on a dry matter basis, since moisture was not always homogeneously distributed between the sachets, and because of the risk of gaining or losing moisture during storage or handling of the samples. CRMs based on Kjeldahl-N can be used to check the performance of Kjeldahl-N determination methods (section 2.1), and also for the calibration of N (protein) determination methods which require Kjeldahl as a reference method (e.g. NIR reflectance, section 2.2). For natural skim-milk powder (CRM 063R) and single-cell protein (CRM 273), only indicative values could be given for Kjeldahl-N, in view of the large spread of results obtained during interlaboratory tests. However, a certified value for total N was obtained for methods based on combustion and/or chemical conversion of N compounds followed by separation and determination of the N₂ formed, e.g. by catharometry.\textsuperscript{180} Two freeze-dried curd reference materials derived from a mixture of ewes’ and goats’ milk and suitable for the detection of adulteration of cheeses made from ewes’ and goats’ milk with cows’ milk are available at IRMM (CRM 599). One material is not adulterated (0%) and the second one contains 1% of cows’ milk. The CRMs can be used in the validation of detection methods which trace cows’ milk proteins in ewes’ and goats’ milk curds, e.g. IEF (section 3.3).

5 CONCLUSIONS

Analysis of N compounds in food is not always a simple task to perform and is often determined by the objective of the analysis. Conventional methods such as Kjeldahl, spectroscopy, and electrophoresis, together with more recent developments such as HPLC, CE, and immunology, offer the analyst a wide choice of techniques. However, all these methods somewhat lack sufficient flexibility to adapt to the chemical complexity in the composition of foods and possible changes of food proteins during manufacturing and processing. This “handicap” is especially prominent in the detection of adulteration of foods, where very low detection limits together with a high degree of certainty is often required. A possible solution is the use of more than one separation technique (two-dimensional analysis). This has been an approach to refine further the identification of wheat varieties.\textsuperscript{181–183} A recent approach is the use of multivariate statistics such as multiple regression, principal component analysis, discriminant analysis, or neural networks, and the use of chemometrics. Applications can be found in the recognition of electrophoretic patterns of wheat proteins\textsuperscript{117,184} and HPLC analysis of...
mixed foods.\(^{(90)}\) As shown, immunological detection is a promising technique, but further research in this area is necessary. For the detection of peptides with a low immunogenicity, formation of antibodies can be increased by conjugation through glutaraldehyde cross-linking to a larger carrier, e.g. hemocyanin\(^{(172)}\) or ovalbumin.\(^{(168)}\) Antibodies raised against E8E, an octapeptide in fragment 141–148 with glutamic acid (E) at the C-terminus (specific for bovine \(\alpha_s1\)-casein) and E8Q, which differs from E8E by replacement of glutamic acid by glutamine (Q) at the C-terminus (specific for ovine, water buffalo, and caprine \(\alpha_s1\)-casein), did not cross-react with the heptapeptide E7P in fragment 141–147 lacking glutamic acid or glutamine at the C-terminus (common in the four species of \(\alpha_s1\)-casein). Addition of extra amino acids to the N-terminus of E8E gave an immune response for anti-E8Q but not for anti-E8Q. Care has to be taken when the antigenicity of peptides is used to detect whole protein fractions in foods. Bovine casein reacted with anti-E8Q although the bovine \(\alpha_s1\)-casein fraction does not contain the E8Q-peptide. This may be due to the presence of interfering compounds in whole casein, which further have to be identified by additional techniques, e.g. immunoblotting.\(^{(134)}\)

PROTEINS, PEPTIDES, AND AMINO ACIDS ANALYSIS IN FOOD

The proximate composition of foods includes moisture, ash, lipid, protein, and carbohydrate contents. These food components may be of interest in the food industry for product development, quality control (QC), or regulatory purposes. Analyses used may be rapid methods for QC or more accurate but time-consuming official methods. Sample collection and preparation must be considered carefully to ensure analysis of a homogeneous and representative sample, and to obtain accurate results. Specific methods of analysis for moisture, ash, lipid, protein, and carbohydrate are described in this article, focusing on the principle of each method, application, and sources of error.

1 INTRODUCTION

1.1 Reasons for Measuring Food Components

Food products produced in the food industry require analysis as part of quality management, product development, or research programs, in efforts to monitor food composition and to ensure the quality and safety of the food. Food components often are measured for the following reasons: (1) formulating and developing new products, (2) evaluating new processes for making food products, (3) identifying unacceptable products, (4) developing or checking a nutrition label, (5) checking the quality of raw ingredients, (6) checking the composition during processing, (7) determining the problem in consumer complaint samples, and (8) checking the composition of competitors’ samples.

1.2 Choice of Methods

The choice of analytical method is dictated commonly by the nature of the sample and the specific reason for the analysis. For example, official methods, which are published by numerous organizations, are used for nutrition labeling purposes or other legal requirements, and generally are more accurate than methods used for rapid QC or in-line processing measurements. Key factors in the choice of method often are speed, precision, accuracy, and durability. Also, it is necessary to validate any method for the specific type of food sample being analyzed.

1.3 Proximate Composition

The proximate composition of foods includes the contents of the macrocomponents, specifically moisture, ash, lipid, protein, and carbohydrate. Other food components, such as vitamins, pigments, flavors, non-nutritive sweeteners, and preservatives, constitute a much smaller proportion of the food. This article covers only the analyses for proximate composition, and not for other food components.
1.4 Sampling and Sample Preparation

All results obtained in analyzing foods depend on obtaining a representative sample and properly converting the sample to a form that can be analyzed.\(^2,9,10\) In general, a sample is collected and analyzed to estimate the quality characteristics of the entire population. The sampling technique must be selected carefully to obtain accurate and precise estimates of the quality of the population. Selection of the sampling procedure is determined by the purpose of the analysis and the nature of the food product, test method, and population being investigated. Once selected for analysis, the sample often must be reduced in bulk or particle size by a method such as grinding. In grinding, care must be taken to avoid moisture loss or gain and to avoid contamination by metals from the grinder. Some samples must be protected prior to analysis from enzymatic degradation, lipid oxidation, and microbial growth and contamination.

2 MOISTURE ANALYSIS

The moisture content of foods is important for reasons such as food quality, cost and convenience of shipping, legal standards, and uniformity for expressing other analytical determinations (i.e. dry weight basis).\(^11,12\) Total solids is the term that refers to the dry matter in food that remains after moisture removal. Moisture analysis may seem simplistic, but obtaining accurate and precise data can be very difficult. Numerous sources describe official, rapid, and in-line methods for moisture analysis including the principles, procedures, applications, and sources of error.\(^4-7,11-13\)

2.1 Oven Drying

Oven drying methods for moisture analysis rely on heating the sample under specified conditions to evaporate water, with weight loss equal to the moisture content. Obtaining accurate and precise results depends on careful temperature control, preventing decomposition of other food constituents, preventing splattering or spillage, and complete removal of the moisture. Forced draft ovens, while being an official method for many foods and easy for handling a large number of samples, often require a time and temperature (e.g. 100–130 °C for 1–24 h) that may make the method too slow for QC applications and cause decomposition of other food constituents. Vacuum ovens allow for drying under reduced pressure, to reduce the drying time and decomposition. In microwave oven drying, the sample is placed between two fiberglass pads, weighed on a balance in the microwave oven, then heated using microwave energy under selected conditions of time and power. This method is considered accurate enough for routine moisture determinations, and has the advantage of obtaining results within minutes. Using another fast method, rapid moisture analyzers, the sample on an aluminum pan or filter paper is placed on a digital balance, then heated by an overhead heating element to evaporate moisture.

Microwave drying ovens and rapid moisture analyzers are considerably more expensive than forced draft or vacuum ovens, but the latter two methods require hours compared with minutes for analysis. Results from microwave drying ovens and rapid moisture analyzers are commonly checked against the reference methods using forced draft or vacuum ovens. Errors in moisture analysis (i.e. over- or underestimation) by oven drying methods occur if food particles are too large, volatile compounds are lost, lipids are oxidized, samples are very hygroscopic, food carbohydrates are altered, a crust is formed on the surface of the food, or the sample splatters.

2.2 Distillation

Distillation procedures involve codistilling the moisture in a food sample with a high-boiling-point solvent that is immiscible with water. The mixture that distills off is collected and measured by volume. Reflux distillation with toluene is the most commonly used distillation technique for moisture analysis. The food sample is heated in toluene, the toluene and water are codistilled, the mixture is collected, and the volume of water removed from the food is measured. Distillation methods prevent exposure of the sample to oxygen and cause less thermal decomposition than do oven drying methods, but distillation techniques are not adaptable to the routine testing that is possible with oven drying methods. Distillation methods have the greatest advantage with samples that are high in volatile compounds (e.g. spices) and lipids (e.g. nuts, oils).

2.3 Karl Fischer

The Karl Fischer method is based on a chemical reaction between the Karl Fischer reagent (KFR) and water in the food sample. The reaction involves the reduction of iodine by sulfur dioxide in the presence of water, to cause a change that can be detected visually or with a potentiometer in a volumetric titration of the water-containing sample with the KFR. A coulometric titration is preferable for products with very low levels of moisture. The volume of the KFR used in the titration, along with a KFR water equivalence determined using a primary standard, allow for the calculation of moisture content.

The Karl Fischer method is the preferred method for many low-moisture foods (e.g. dried fruits, candies,
chocolate, and roasted coffee). The method uses no heat and is rapid and sensitive, but is subject to error from interfering food constituents (e.g. ascorbic acid, carbonyl compounds, unsaturated fatty acids). Other sources of error include incomplete water extraction, atmospheric moisture, and moisture adhering to the wall of the Karl Fischer unit.

### 2.4 Physical Methods

Physical methods used commonly for a rapid determination of moisture content in foods include hydrometry, refractometry, and infrared (IR) spectroscopy. These methods do not involve the removal of water as is used in oven drying or distillation methods, or the chemical reaction of water as is used in the Karl Fischer method. In contrast, physical methods relate certain physical properties of the food to the moisture content. Some physical methods can be applied directly in the food processing line, for immediate control of the moisture/solids content.

#### 2.4.1 Hydrometry

Hydrometry, the science of measuring specific gravity or density, is used commonly for rapid routine testing of moisture/solids content of foods such as beverages, salt brines, and sugar solutions. While a pycnometer or Westphal balance are used sometimes to measure the specific gravity of foods, various types of hydrometers are used most commonly. These include a lactometer for milk, Brix hydrometer for sugar solutions, Baumé hydrometer for alcohol content of beverages, and Twaddell hydrometer for liquids heavier than water. A hydrometer is based on Archimedes’ principle, which states that a solid suspended in a liquid will be buoyed by a force equal to the weight of the liquid displaced. The volume of test liquid displaced by an object of standard weight (i.e. hydrometer) is measured to determine the weight per unit volume of the liquid. The hydrometer placed in the liquid displaces a weight of liquid equal to its own weight. The relative density (i.e. specific gravity) of the sample is compared with that of water at the same temperature. The spindle of the hydrometer is calibrated to read specific gravity directly at 15.5 or 20°C. This method requires temperature control and the use of a clean hydrometer.

#### 2.4.2 Refractometry

Refractometry is based on the bending of light (i.e. refraction) as it passes from one medium (e.g. air) to another (e.g. food product). The bending of the light beam is a function of the media and the sines of the angles of incidence and refraction at any given temperature and pressure, and is thus a dimensionless constant that can be used to describe the nature of the media. This constant, the refractive index (RI), is the ratio of the sines of the angle of incidence and the angle of refraction. All chemical compounds have a characteristic RI. The RI varies with concentration of the compound, temperature, and wavelength of light. Therefore, by holding the temperature and wavelength of light constant, one can use the RI to determine the concentration of the compound of interest. Refractometers are commonly used as a rapid method to determine the moisture (total solids) content of liquid sugar products and condensed milk and the soluble solids content of fruits and fruit products. Abbe refractometers are popular benchtop units for laboratory use, but hand-held units are convenient for rapid testing at the processing line, and refractometers can be installed directly in a liquid processing line. Because of their application in determining solids contents of carbohydrate-based foods, refractometers are calibrated in °Brix (g of sucrose/100 g of sample).

#### 2.4.3 Infrared Spectroscopy

IR spectroscopy can be used to determine not only moisture content of foods, but also lipid, protein, and carbohydrate contents. This method measures the absorption of radiation (near- or mid-IR) by molecules in foods. Different functional groups characteristic of the molecules in food absorb different frequencies of IR radiation. A sample is irradiated with a wavelength of IR light specific for the constituent of interest. The energy that is reflected or transmitted by the sample, which is inversely proportional to the energy absorbed, is measured as an indicator of the concentration of the food constituent. For accurate results, the IR spectrometer must be calibrated for each analyte to be measured, and the analyte of interest must be uniformly distributed in the sample. IR spectroscopy has a wide range of food applications, and has proven successful in the laboratory, at the processing line, and in-line.

### 3 ASH ANALYSIS

Ash in a food product represents the total mineral content, and refers to the inorganic residue remaining after either ignition or complete oxidation of organic matter. Ash determination is part of the proximate analysis for nutritional evaluation, and is the first step in the preparation of a food sample for the analysis of specific minerals. Ash content of foods is determined most commonly by dry, wet, or microwave ashing methods. Many food products must be dried and/or ground before ash analysis. Sources of error for these
methods include use of an unrepresentative sample, loss of samples in a drying step before ashing, contamination with minerals, volatilization of elements, and incomplete combustion of organic matter.

3.1 Dry Ashing
In dry ashing, the sample is placed in a crucible and heated in a muffle furnace to a high temperature (500–600 °C). This incinerates all the organic matter, leaving inorganic material to be quantitated gravimetrically. The procedure is time-consuming (12–18 h) and loss of volatile elements is a risk, but the procedure is simple and a large number of samples can be handled at one time.

3.2 Wet Ashing
In wet ashing, the organic matter in a sample is oxidized using acids and oxidizing agents, leaving only inorganic matter. This is a liquid treatment that uses low temperatures, compared with the high temperature and drying conditions of dry ashing. Wet ashing is used primarily to prepare a sample for analysis of specific minerals because the minerals usually stay in solution and there is little or no loss from volatilization. However, wet ashing requires almost constant operator attention, a limited number of samples can be handled at one time, corrosive reagents are necessary, and an appropriate fume hood is required. If perchloric acid is used in the procedure, special precautions and facilities are required.

3.3 Microwave Ashing
Microwave systems are available for both wet and dry ashing. Programmed microwave wet digesters and muffle furnaces can dehydrate then ash the sample and exhaust the system. The time for analysis is reduced from hours with conventional dry ashing to minutes, but a limited number of samples can be processed at one time.

4 LIPID ANALYSIS
The term lipids refers to a wide range of compounds soluble in organic solvents but only sparingly soluble in water. The terms lipids, fats, and oils sometimes are used interchangeably, but fats and oils are distinguished generally by whether they are solid or liquid at room temperature. The lipid content of foods is determined commonly by solvent extraction methods, but wet extraction methods without an organic solvent are applicable to liquid samples. As alternatives, rapid instrumental methods based on various principles have been developed for lipid analysis.

4.1 Solvent Extraction
Prior to using solvent extraction methods, samples may need to be subjected to drying, particle size reduction, and acid hydrolysis. The last treatment is used because a significant portion of lipids in some foods is bound covalently or ionically to proteins and carbohydrates, which makes direct extraction with solvents inefficient. In solvent extraction methods, the fat is extracted from the food sample with a solvent (e.g. diethyl ether, petroleum ether). Fat content is measured by weight loss of the sample or by the weight of fat removed.

4.1.1 Traditional Methods
The traditional solvent extraction techniques can be classified as continuous, semicontinuous, or discontinuous. The Goldfish method is continuous, with the solvent from a boiling flask continuously flowing over the sample held in a ceramic thimble. The Soxhlet method is semicontinuous, with solvent from the boiling flask being volatilized and condensed to build up in the extraction chamber that holds the sample. The sample becomes completely soaked with solvent before the solvent siphons back to the boiling flask. The Mojonnier method (similar to the Roese–Gottlieb method) is discontinuous, uses a combination of solvents, and does not require prior removal of moisture from the sample. In this method, the sample is treated in series with ammonia solution, 95% ethanol, diethyl ether, and petroleum ether. The solvent-soluble material is poured from the Mojonnier flask into a drying dish. After a second and third series of extractions are performed, the combined solvent-soluble material is dried to evaporate the solvent, leaving the fat to be determined by weight.

4.1.2 Rapid Methods
Lipid solvent extraction methods utilizing microwave energy, high pressure, or high temperature have been developed to reduce the time required for analysis and reduce or eliminate solvent usage. With these methods, the initial investment in instrumentation is considerable compared with traditional methods, but there are great savings in time and solvent usage.

In microwave-assisted solvent extraction, the sample is dried in a microwave oven, extracted with mechanical agitation (e.g. 6 min), and redried in the microwave oven to evaporate the solvent. In supercritical fluid extraction (SFE), a fluid (usually CO₂) is brought to a specific pressure–temperature combination. This allows it to attain supercritical solvent properties to extract fat selectively from the sample. The fat dissolved in the supercritical fluid is precipitated by decreasing the pressure of the solution, so the precipitated fat can
be dried and weighed. In accelerated solvent extraction, the fat is extracted when the sample is exposed to a nonpolar solvent in a static (i.e. no outflow of solvent) or dynamic (i.e. fresh solvent continuously flows through the sample) mode, under elevated temperature and pressure conditions. The solvent is then evaporated from the extracted fat, and the fat is dried and weighed.

4.2 Wet Extraction Without Organic Solvent

The Babcock and Gerber methods were developed for lipid analysis of dairy products, and utilize acid treatment rather than the use of an organic solvent. In the Babcock method, the sulfuric acid added to the sample in a Babcock bottle digests protein, generates heat, and releases the fat. With centrifugation and hot water addition, fat rises to the graduated portion of the test bottle so it can be quantitated by volume. The Gerber method is similar, but uses both sulfuric acid and amyl alcohol.

4.3 Instrumental Methods

As described above, IR spectroscopy can be used to predict the lipid content of foods. Mid-IR spectroscopy is used in IR milk analyzers to determine milk fat content. Near-IR spectroscopy has been used to measure the fat content of meats, cereals, and oilseeds, and is being adapted for in-line measurements. Other rapid instrumental methods for fat analysis are based on acoustic properties of the fat (i.e. ultrasonic method), X-ray absorption of fat, the dielectric constant of the food as affected by lipid content, specific gravity, and light scattering caused by fat globules.

5 PROTEIN ANALYSIS

Protein analysis is important for nutrition labeling, assessing nutritional value, and during isolation and purification of a protein. Protein content methods based on nitrogen content are typical official methods of analysis, but wet chemistry methods, based on other principles, and rapid instrumental methods are used for other applications.\(^{18–20}\)

5.1 Nitrogen Content Methods

The Kjeldahl and Dumas methods are both based on determining the nitrogen content of the sample and using that value to calculate protein content. In the Kjeldahl method, proteins and other organic food components are digested with sulfuric acid in the presence of catalysts, with organic nitrogen being converted to ammonium sulfate. The digested sample is neutralized with alkali and distilled into a boric acid solution. The boric anions formed are titrated with standardized acid to a specific pH or color. The volume of standardized acid used in the titration is used to calculate the nitrogen content of the sample, and that value is converted to crude protein content. In the Dumas, or nitrogen combustion, method, the sample is combusted at high temperatures (700–800°C). The nitrogen released is measured by gas chromatography using a thermal conductivity detector. The nitrogen value is converted to protein content. For both the Kjeldahl and Dumas methods, nitrogen to protein conversion factors are appropriate for certain specific foods, but the general factor used is 6.25 (100/16 = 6.25, since most proteins contain 16% nitrogen).

Both the Kjeldahl and Dumas methods can be applied to all types of foods; total organic nitrogen is measured and not just protein nitrogen. The Kjeldahl method has been an official method for crude protein content for many years, and the Dumas method is increasingly being approved as such. Unlike the Dumas method, the Kjeldahl method uses corrosive reagents and is time-consuming. The Dumas method utilizes an expensive instrument, but results are available within minutes and automated instruments can analyze over 100 samples without attention.

5.2 Infrared Spectroscopy

Whereas mid-IR spectroscopy is used widely to determine the protein content of milk, near-IR spectroscopy is applicable to a wide range of food products. Wave-lengths of IR radiation characteristic of the peptide bond are used to estimate the protein content, by the procedure for IR spectroscopy described above. Although such instruments are expensive and must be calibrated properly, samples can be analyzed rapidly.

5.3 Other Methods

Numerous wet chemistry methods to measure protein content rely on various principles: peptide bond, aromatic amino acids, ultraviolet absorbivity of certain amino acids, free amino groups, light scattering properties, and dye-binding capacity. Many of these methods are most applicable to the research laboratory. For example, measuring absorbance at 280 nm, which is based on the presence of tyrosine and tryptophan, is a qualitative, nondestructive method applied to protein samples as they elute from a chromatographic column. The bicinchoninic acid (BCA) method is a quantitative, sensitive, destructive method based on the fact that proteins reduce cupric ions to cuprous ions under alkaline conditions.
The cuprous ion complexes with the BCA reagent to form a purplish color that is proportional to the protein concentration.

6 CARBOHYDRATE ANALYSIS

Total carbohydrate content is of interest for nutrition labeling purposes and for samples in a research laboratory. However, of more use in developing food products and ensuring their quality may be the content of specific carbohydrates or groups of carbohydrates. The content in foods of specific mono- and oligosaccharides may be determined by enzymatic assays or high-performance liquid chromatography (HPLC). Starch and total dietary fiber contents of food are determined by methods that utilize enzymes.\(^{1}\)\(^{2}\)\(^{–}\)\(^{2}\)\(^{5}\)

6.1 Total Carbohydrate

Total carbohydrate content for nutrition labeling purposes is calculated by difference after determining all other components of proximate composition (Equation 1):

\[
\text{total carbohydrate} = 100\% - (\% \text{ moisture} + \% \text{ ash} + \% \text{ lipid} + \% \text{ protein}) \quad (1)
\]

However, a phenol–sulfuric acid method is used commonly in research laboratories to determine the total carbohydrate content of samples. In this method, carbohydrates are heated in the presence of concentrated sulfuric acid to produce furan derivatives. These derivatives condense with phenol to form compounds that can be quantitated spectrophotometrically. Absorbance values are related to a calibration curve developed using a single sugar.

6.2 Mono- and Oligosaccharides

The food content of carbohydrates such as glucose, fructose, sucrose, lactose, maltose, raffinose, or stachyose may be of interest. Samples may require extraction before analysis of total reducing sugars or individual sugars by HPLC or enzymatic methods.

6.2.1 Extraction

Extraction is used to remove interfering substances from samples prior to analysis for mono- and oligosaccharides. The most common procedure used is extraction with hot 80% ethanol (final concentration), in which mono- and oligosaccharides are soluble but polysaccharides and proteins are insoluble. Calcium carbonate is added to neutralize any acidity, so sucrose is not hydrolyzed to glucose and fructose. The 80% ethanol extract will contain components other than carbohydrates, which can be removed by ion-exchange techniques if necessary. The aqueous alcohol of the ethanol extract can be removed under reduced pressure at low temperatures using a rotary evaporator.

6.2.2 Reducing Sugars

Reducing sugars are those mono- and oligosaccharides that contain a free carbonyl (aldehyde or ketone) group, so can act as reducing agents. These sugars are of interest because they can react with proteins to cause Maillard browning in foods. The Somogyi–Nelson, Munson–Walker, and Lane–Eynon methods all can be used to measure reducing sugars, and are based on the reduction of cupric ions in alkaline solution to cuprous ions by reducing sugars. In the Somogyi–Nelson method, which is the most often used method, the amount of cuprous ions generated in the reaction with reducing sugars is quantitated in a second oxidation–reduction reaction that produces a colored complex that can be measured spectrophotometrically. Glucose or another specific reducing sugar is used to generate a calibration curve for comparison.

6.2.3 High-performance Liquid Chromatography

HPLC is the most commonly used chromatographic method to quantitate specific mono- and oligosaccharides. Stationary phases most often used for HPLC are anion-exchange, cation-exchange, normal-phase, and reversed-phase materials. Detectors most commonly used for such analyses are RI, electrochemical (pulsed amperometric), and postcolumn derivatization with absorbance or fluorescence detection.

6.2.4 Enzymatic Assays

Enzymatic methods have been developed to quantitate specific monosaccharides (e.g. fructose, glucose, galactose), oligosaccharides (e.g. lactose, maltose, sucrose), and polysaccharides (amylose, amylopectin, β-glucan, inulin, starch). For many of these, commercial kits are available that contain appropriate enzymes, other required reagents, buffers, and detailed instructions. In these enzymatic assays, enzyme concentration, substrate concentration, concentration of other required reagents, pH, and temperature must all be controlled because they will affect the reaction rates and results. Enzymatic methods usually are very specific for the substance being measured and have low detection limits. However, care must be taken to remove interfering compounds present. The enzymatic methods are useful to quantitate individual specific carbohydrates, but not for measuring total carbohydrates, a class of carbohydrates, or all carbohydrates individually.
6.2.5 Physical Methods
As described above for moisture/solids analysis, specific gravity, refractometry, and near-IR spectroscopy can be used to measure carbohydrate content of some types of foods. Polarimetry is another physical method applicable to carbohydrates. Carbohydrates, like most other compounds that contain one or more chiral carbon atoms, will rotate the plane of polarization of polarized light. The extent to which a compound in solution will rotate the plane of polarized light can be measured with a polarimeter. When the nature of the compound, temperature, and wavelength of light are kept constant, the concentration of the compound can be determined by measuring optical rotation. For example, the process of hydrolyzing sucrose into D-glucose and D-fructose can be monitored by determining the specific optical rotation before and after sucrose hydrolysis. The methods of polarimetry, refractometry, and specific gravity are applicable only for liquids, and are accurate only for solutions of pure sucrose or other sugars.

6.3 Starch
The starch content of a food is best determined by a combination of enzymes in sequential enzyme-catalyzed reactions. Starch is converted totally to D-glucose by enzymes specific for starch (amylases), then D-glucose is quantitated enzymatically (e.g. combination of glucose oxidase and peroxidase). Two cautions are that the amylases must be pure, and the assay may not be quantitative for high-amylose starch or samples high in starch resistant to digestion.

6.4 Dietary Fiber
Dietary fiber constituents are cellulose, lignin, hemicellulose, pectins, and hydrocolloids. Some of these constituents are soluble in water and some are insoluble. These constituents in total are measured by the official method for total dietary fiber, which is an enzymatic–gravimetric method. A dried, defatted sample is enzymatically digested with α-amylase, amyloglucosidase, and protease to remove the starch and protein. The soluble fiber components are precipitated by adding ethanol. Soluble and insoluble fiber components are collected as the residue upon filtration. The weight of the dried residue, corrected for ash and protein contents (determined by dry ashing and the Kjeldahl method, respectively), is used to calculate the dietary fiber content.

ACKNOWLEDGMENTS
The author thanks the authors of the chapters on sampling, and on moisture, ash, lipid, protein, carbohydrate, and fiber analysis from the book she edited. These chapters were invaluable in writing this article.

Sample preparation is one of the important steps in flavor and food analysis. Thermal extraction (TE) of volatile substances simplifies sample preparation by separating volatile from nonvolatile compounds. A temperature vaporizing program allows additional prefractionation of the analytes. SV supports chromatography by removing a large amount of solvent. In this way, interfering and problematic ingredients in the sample can also be removed, while the analytes of interest are absorbed onto a specific stationary phase placed in a cryotrap. Sample preparation by SFE is discussed with respect to the specific advantages and disadvantages of several other techniques. Solid-phase micro-extraction (SPME) and accelerated solvent extraction (ASE) are also covered. Unambiguous control of the sample determination is carried out by mass spectrometry (MS). The coupling of high-performance liquid chromatography (HPLC) with MS is an established standard technique. Capillary electrophoresis (CE) coupled with MS is a relatively new development, and CE has yet to establish itself as a routine analytical method. However, current developments in this technique have demonstrated its potential use in the near future.

2 HYPHENATION TO GAS CHROMATOGRAPHY

2.1 Thermal Desorption

Thermal desorption (TDS) is the extraction of compounds by their vapor pressure from a nonvolatile, complex matrix. The sample is placed into a specifically designed glass tube which is inserted into a system with temperature control from $150^\circ$C to $250^\circ$C. The carrier gas flow over the sample can be controlled over the same temperature range. The cooled GC liner can also be filled with adsorbent material in order to trap the analytes quantitatively. This additional focusing mechanism is known as the cooled injection system (CIS). For TDS, the influence of temperature and carrier gas flow are the most important parameters. The flow can be set to such high rates that compounds of low volatility, i.e. having very low vapor pressures, can be transferred to the injector. Higher temperatures can be used when thermally sensitive substances are present. The temperature can be set so that thermally sensitive compounds are desorbed at low temperatures. Then the TDS process can be set to a higher temperature so that desorption occurs of molecules with lower vapour pressures. Desorption of polar compounds with high boiling points is possible. For example, the desorption of glycerol (having a boiling point of $290^\circ$C), takes place with a high carrier gas flow (Figure 1).

An additional SV feature reduces chromatographic interference by the solvent; the analytes are trapped in the CIS. The split valve is open in SV mode. The thermally extracted volatiles enter the liner and the analytes are...
trapped in the CIS at a very low temperature, while the solvent is vented through the split outlet. The venting of the solvent is dependent on the temperature and the carrier gas flow. Too high flow rates will result in loss of analytes. If the trapping temperature cannot be set low enough, it is possible to trap the analytes by placing an adsorbent into the liner (e.g. Tenax®, Porapak®). This option also enables the use of higher (e.g. ambient) temperatures.

When the desorption process is complete, the injection is carried out by heating up the liner to transfer the sample to the analytical column. Mild desorption conditions can be achieved by heating in a suitable temperature gradient. The desorption is also very mild when other compounds are present that can form azeotropes with the analytes. At less steep temperature gradients, peak broadening has to be taken into consideration when choosing the cryotrap parameters.

The analysis of fragrance in an air freshener stick which contained a wet soapy matrix was analyzed without any sample preparation by TDS. If carried out by classical extraction, this analysis would require extensive sample clean-up. Sample preparation consists of weighing the sample and placing it in the TDS tube. The weighing should take place quickly because recovery rates are influenced by the exposure time to air. This has a stronger influence on the recoveries of highly volatile compounds than loss in the CIS. The recovery rate has to be determined for each compound. Quantitation is best achieved by adulteration of the sample with a quantity of the analyte comparable to the amount present in the sample. External standard quantitations give reliable results only when the standard is applied to the same matrix. This is because sample recovery is strongly dependent on the polarity of the analyte and the matrix. Figure 2 shows the result of the analysis of an air freshener.

The fragrance of a shampoo was injected to determine the recovery of all fragrance compounds from the matrix. It was observed that most compounds were extracted quantitatively, but a few compounds were hardly recovered. This may have several reasons: too long venting time, too high trap temperature, or incompatibility between the adsorbent material and these molecules. Incompatibility here means that the compounds are not retained in the trap on the adsorbent and are lost through the solvent split, or that they are not released from the adsorbent because a strong binding interaction takes place between the compounds and the trapping material. These observations make it necessary to carry out a thorough quantitation, as described above.

Analysis of autoxidation products in moisturizing creams with a considerable amount of water can be carried out by placing the sample into the TDS tube and thermally desorbing using SV to reduce the problem of interfering compounds, such as water. A temperature of 80 °C is low enough not to also desorb the fat, and only the analytes are transferred to the injection system. The low content of these analytes can be overcome by using a large volume of oil in order to obtain enough analyte to be determined. A difficult analysis using TDS alone is when the sample contains a considerable amount of water. In this case it is necessary to use an off-line TE instrument.

A difficult analysis using TDS alone is when the sample contains a considerable amount of water. In this case it is necessary to use an off-line TE instrument.

The analysis of fresh ginger roots by TDS is an example of the moderate conditions that are applied during sample extraction by TDS. Conventional sample preparation for the analysis of essential oils is carried out by steam distillation. This exposes the analytes to high temperatures for quite a long time in the distillation vessel, with the potential risk of degradation. TE can be used to remove most of the water content in a short period of time. This is necessary because the analysis is carried out on a polar (wax) column. The desorption is so mild that thermally sensitive compounds can be detected in much higher concentrations than expected from the literature. Figure 3 shows the analysis of fresh ginger roots.

Figure 1 Principle of TDS.

Figure 2 TDS of an air-freshener stick which contained a wet, soapy matrix.

Figure 3 TDS of an air-freshener stick which contained a wet, soapy matrix.
TDS does not require knowledge of the physicochemical properties of the analyte, and in most cases leads to good results more quickly. For individual compounds the extraction efficiency and recovery rate of TDS has to be determined by spiking the sample with the compound of interest. The amount of spiking material must be in the same range as in the sample.

TDS is a new and powerful sample preparation technique. The appropriate approach to sample preparation depends on the compounds that need to be quantified, and on the sample matrix. Used correctly, a wide range of compounds can be determined in a reliable and reproducible way.

2.2 Thermal Extraction
TE is an off-line TDS with a TDS tube as focusing device. The focusing is carried out by an appropriate absorption material. This device is used when the original sample contains considerable amounts of water. Otherwise, the TDS procedure can result in severe losses of analytes when the temperature is not low enough. Also, when the temperature of the cryotrap is below 0 °C, the water in the sample would freeze immediately and block the system. In principle it is possible to extract pesticides from an aqueous sample by this technique (Figure 4).

2.3 Supercritical Fluid Extraction
SFE as an alternative extraction method without solvent consumption is comparable to TDS. This technique is particularly useful in the extraction of hydrophobic compounds. Even low-volatile compounds are extractable under very mild conditions. The recoveries are comparable to the results obtained with TDS for nonpolar compounds. For polar compounds an additional modifier is added to the supercritical fluid. The extraction efficiency of SFE and TDS is comparable for polar compounds. Usually the same solvent is used as applied for the rinse step from the trap. Extracts obtained by SFE are compatible with several separation techniques, such as gas chromatography, HPLC, or capillary electrophoresis. However, TE is designed specifically for use with gas chromatography.

The extraction of hydrophobic compounds from complex matrices containing sugar, proteins, and fat can be achieved almost quantitatively, but polar molecules give poor recovery rates. The recovery of these compounds can be improved significantly by the addition of a modifying solvent.

Changes in the density of supercritical fluids influence the extraction of nonpolar compounds of different molecular weight. These compounds can be fractionated in a short period of time by the correct choice of density.

2.4 Supercritical Fluid Extraction with a Modifier
The addition of a modifying eluent such as acetonitrile or methanol enables other compounds to be extracted by SFE. Thus selection by polarity provides an additional fractionation parameter.

There are two possibilities when adding a modifier: static addition of modifier directly into the extraction thimble, and addition of the solvent by a modifier pump. The pump delivers a constant flow rate and improves extraction efficiency and reproducibility. Modification can also mean addition of an adsorbent to the sample to retain specific substances that are problematic to the analysis.

For example, at low densities, the extraction of flavors out of a fatty matrix can be achieved by adding cellulose powder to the sample. Supercritical carbon dioxide then extracts the flavoring compounds without any of the problematic sample matrix compounds, such as fatty acids or triacylglycerols. After SFE extraction, the analysis can be carried out by gas chromatography, HPLC, or CE. The recovery of terpenes from a hydrophobic matrix by SFE can be as high as 80%. For more polar compounds the addition of a modifier is essential for SFE.

2.5 Solid-phase Microextraction/Headspace Gas Chromatography
SPME represents a special technique for the absorption for volatile compounds. The technique is very specific and has to comply with the physical and chemical properties of the analytes. If the properties of the analytes are
known the absorption material can be chosen correctly and the analysis shows both high selectivity and high sensitivity. The principle of the technique is shown in Figure 5. The absorbent material may be located in the headspace above the sample or can be immersed in the solvent containing the analyte. The latter variation is more critical because the absorption material can become saturated by the solvent, thus changing the material’s properties.

2.6 Accelerated Solvent Extraction

ASE is similar to SFE. The difference is that organic solvents are used instead of supercritical fluids. The use of temperature and pressure as variables, together with a choice of organic solvent, extends this extraction method to include polar materials, which are usually covered by conventional extraction methods with polar solvents. Compared to liquid–liquid extraction, this technique shows a higher efficiency (i.e., recovery rate) in a shorter time. With an organic solvent such as acetonitrile, the extraction of polar metal ion complexes from soap was almost as efficient as extraction by SFE with a modifier. Compared to Soxhlet extraction or continuous liquid–liquid extraction, the time required was reduced 10-fold. This technique is most effective when the physicochemical properties of the molecules and the matrix are known, thus requiring a detailed understanding of the underlying chromatography.

3 CONCLUSIONS

The extraction methods described in this article extend the range of applicability to fast and specific extraction efficiency for known compounds. These new approaches deal with very specific conditions in which the matrix and the properties of the compounds influence extractability and recovery. Data evaluation can only be considered reliable when a quantitation of the analytes has been carried out according to accepted guidelines.

Sample Preparation for Food Analysis, General

Michael J. Lichon  
University of Tasmania, Hobart, Australia

1 Introduction

With few exceptions, matrices containing analytes are complex, inhomogeneous mixtures of a large range of chemical substances which may include intermediate and side reaction products. The isolation and measurement of the individual chemical compounds of interest usually represent a difficult challenge, particularly with modern requirements for environmental management and food standards. Even with powerful modern techniques of separation and identification, such as high-performance liquid chromatography (HPLC), rarely is it possible to load a syringe directly with an intact matrix and inject to obtain a sensible result. Perhaps surprisingly, it is not unusual to find analytical methods published with precision data reflecting repeated direct assays of standard solutions. This tells the reader little about the practicality of the methods with regard to real-world samples. Analytical errors usually cost money: wrong decisions based on erroneous results, lost business, false security, litigation, etc. The identification and minimization of sources of error, of which sampling and sample preparation usually feature prominently, need special attention and resources. Procedures for preparation of the sample should be developed, evaluated and published as an integral part of any analytical method and application.

Three basic steps are involved in sample preparation for chemical analysis: (1) sampling, obtaining a sample for the laboratory; (2) homogenization of the laboratory sample to permit the taking of test portions; and (3) sample preparation, physical and chemical manipulation of the test portion prior to analytical measurement. It should be appreciated that elements of these steps may occasionally occur in the reverse order or as combined operations. The fourth and final step of the analysis is the actual determinative assay procedure. Paradoxically, although the purpose of each of the three steps is to increase the accuracy and precision of the analysis so the test portion reflects the composition of the bulk, each step also introduces inherent errors. The error contributions of these steps for a typical analysis scheme are shown in Figure 1. Analyte concentration is limited at one end by detection limit and at the other by overloading of preparation stages or the measurement instrument by either analyte or matrix. The significance of the contributions of these steps to the total error for the analysis are mathematically described by the relative standard deviation (RSD) relation (Equation 1):

\[
RSD_{\text{total}} = (RSD_{\text{sampling}}^2 + RSD_{\text{homogenization}}^2 + RSD_{\text{sample preparation}}^2 + RSD_{\text{analytical}}^2)^{1/2}
\]  

(1)
This equation shows the errors to be additive. Either a greater number of preparative steps or larger errors in a smaller number of steps may create a worse overall error. Furthermore, the errors of each step are not only cumulative, but also usually strictly irreversible. Any error generated, by sampling (for example), can usually not be compensated for by any subsequent treatment.

From Equation (1), it is clear that if any one of the contributing factors is significantly greater than the others, it is futile to attempt to reduce any of the other contributors, as the total error will be disproportionately dictated by the most dominant factor being squared. A good example is aflatoxin analysis of bulk peanuts, where as long as the sampling error contributes 90% of the error there is little incentive to improve the analytical precision beyond academic interest.

It may often be clear to an experienced analyst what the approximate proportions of the contributing errors are of the total for a familiar analysis. If this is not so, these may be defined by rigorous assays of replicates and recoveries testing the effects of each successive step of the analysis. This review of preparing samples for chemical analysis is divided into three sections to consider problems encountered in each of these respective steps. Examples are drawn from food and environmental analysis from the author’s experience of these arguably more challenging fields of analytical chemistry.

2 SAMPLING FOR ANALYSIS

There has been great concern amongst analysts over the validity of analytical methods. Attempts to define rigorously the precision and accuracy of methods include measures such as international collaborative trials. For all the benefits of implementing such expensive measures there is one important oversight: the issue of sampling is not examined. Experience demonstrates that sampling can often be the greatest source of error in chemical analysis, particularly for environmental and food matrices (Figure 1). Frequently lack of attention to sampling is the hidden factor behind “unexpected” analysis results.

The classic example of incorrect sampling procedure and its ridiculous consequences is given by the fable of the blind men and the elephant. The consequences are sometimes no less ridiculous for incorrect chemical sampling.

W.J. Blaedel and V.W. Meloche

Undergraduate texts often form the basis of analysts’ future attitudes. The spectrum of emphasis on sampling ranges from serious but brief mentions through a good treatment, but at chapters at the end of the book to an integral treatment from the beginning. This choice resides with course designers and coordinators. Unfortunately, in the real world, the benefits of correct sampling come at a cost. However, if one considers the assay of a sample that does not represent the bulk, or “population”, of interest as near useless, then to obtain meaningful analytical data one must be prepared to pay for it. If the samples, individually and collectively, cannot provide the required information, they are seldom worth the time and expense of analysis. Correct sampling by competent personnel may require an investment of anything up to, or even more than, the cost of the laboratory assays. Planning for informative sampling must be an integral part of any study. Subsequent occasions of analysis of the same situation may cost somewhat less on account of experience.

2.1 Aims of Sampling

The degree of justifiable investment often depends on the purpose of the assay: for assay leading to the determination of a market price of a shipment, it may well be acceptable to spend 1% of the market value of the commodity on reliable sampling. Although this may at first seem a high cost, it may be low when regarded as an insurance policy against larger losses. If a pesticide content of an export shipment of beef is suspected to approach the acceptable threshold, the sampling could...
justify a far higher expense than, for example, when routinely examining for other contaminants known to be far below regulatory limits.

The best method of sampling in a given situation will depend on such issues as what information is sought, resources available, accessibility of the target population, what the required turnaround time is, perishability of the matrix and the analyte, what the criteria are for acceptability and sampling correctness, whether samples are to be pooled or replicated, whether analysis should be performed separately on different portions of the sample, whether the surface is to be included in the bulk and the monitoring which should occur to prevent contamination and abuse.

The compilation of food composition data presents specific sampling problems. Typically cited nutrient contents frequently reflect limited localized sampling.\(^{(12)}\) The task of nationwide representative sampling is fraught with bias, difficult to organize and resource intensive.

Environmental monitoring may frequently best involve indirect sampling, e.g. of animals, such as trout or molluscs which accumulate heavy metals from the environment. Hair or blood of mine workers may be analyzed to estimate exposure to ore dust as less intrusive than biopsy sampling of vital organs or bone accumulation. Breath or urine samples are commonly used to estimate blood concentrations of drugs. Accumulator plants have been used as indicators for mineral prospecting. Foods such as milk, through which children may be particularly exposed to some pollutants, are often the subject of monitoring programs.\(^{(3)}\)

Production sampling may seek to determine a market price based on positive analytical content (such as Cu and Ag in a bulk mineral concentrate) or to price-set or outright select against contaminant content (mycotoxins, pesticides, etc., in foods).

### 2.2 Nature of Matrix and Analyte

Is the matrix/population really heterogeneous? A poignant example of an apparently homogeneous flowing liquid showing unexpected variation is shown in Figure 2. Is spatial variation general, localized or stratified? Should the population be sampled critically or representatively, randomly or systematically? Table 1 offers some consideration of this question. The low bias of random sampling has obvious attractions, and may be desirable to minimize sampler’s liability. Systematic grid sampling is particularly useful in measuring changes over time;\(^{(13)}\) an example being monitoring soil fertility changes. Targeted sampling may be robust if the background research shows that the analyte of interest is associated with a readily identifiable feature of the matrix and only spot measurements of high or low analyte provide the required data. Is there temporal variation, and over what scale of

time? What factors influence the changes? The example in Figure 3 demonstrates unexpected analyte fluctuations in dam overflow samples due to overestimating the optimum sampling regime timescale – some fluctuations may well be missed by the data.

The difficulties of obtaining good representative sampling depend on the nature of the “population”. Discrete populations are relatively easy to sample. In the case of a shipment of pallets of canned food, the units are discrete and may be mathematically modeled and sampled; the only inconvenience then is the necessity for dismantling some of the pallets to extract the desired target cans. This correct procedure is often bypassed, and cans are taken from the top corner of the most accessible pallets to give a highly biased sampling.

Sampling of continuous populations is by far more common. Most difficult sampling problems usually involve a 3D bulk population: simple sampling is rarely possible.\(^\text{(11)}\) A more reliable approach is to convert the bulk into a one-dimensional flowing stream. The stream is then divided systematically, randomly, or by a combined formula of random delineation of systematic segments, into target segments in time, such that any part of the bulk has an equal probability of scrutiny.\(^\text{(11)}\) Entire cross-section segments (strictly delineated by parallel planes) of the stream are sampled at the target times, then taken either separately or pooled for analysis. In a factory situation, the best sampling points are often conveyor belts, from which segments may be easily extracted. Another method of treatment of a three-dimensional bulk is to convert it into a flattened two-dimensional configuration. The two-dimensional bulk may then be sampled by cylindrical corer, at random or systematic points on the surface, ensuring that the entire thickness of the bulk is recovered. In practice, this method often fails to recover a strictly delineated cylindrical core, or adequately to expose the bottom of the bulk to scrutiny by virtue of the device being unable to retrieve the lowest part of the cylinder. The two-dimensional bulk may be fashioned into a long narrow pile, and cross-sampled in space as a one-dimensional bulk, with randomly or systematically located segments delineated by parallel planes. The classical method of coning and quartering can rarely be done correctly (fundamental problems of delimitation and by unmixing, both spontaneously and when being moved; see section 3.2), and operator bias further fails the process.\(^\text{(11)}\)

It may on some occasions be desirable to analyze unrepresentative target, or extreme portions of a population, as well as a representative sample (Table 1). It may be of interest to find extreme values for vitamins, to find the worst case for environmental contamination, or to link distribution with a causative factor. It may be desirable to select specimens with a view to breeding selection.

To consider some additional variables in real sampling problems, take the example of analysis of peas: sample variables include size distributions, position of individual peas in their pods, height of pods up the individual vine, individual plant genetics, cultivar, time of planting, efficiency of pollination, watering history, soil type and underlying geology, previous crop history, soil fertilization, crop maturity, disease and pestilence attack, length of time and handling and storage conditions since harvest. Some further questions follow: will either the sample deteriorate or the data expire before the sampling, analysis, and reporting are complete?; are the peas to be cooked?; if so, how and for how long?; is the analysis to represent data for a single plot, farm, locality, or national database?; does the sampling need to be certified, for legal or economic reasons?

The importance of sampling is highlighted by problems encountered in analysis of aflatoxins in peanuts. Several workers have specifically addressed this difficult sampling situation.\(^\text{(2,14–17)}\) The highly inhomogeneous distribution of analyte in the matrix leads to the proportion of total analytical error attributable to sampling commonly exceeding 90%. Similar distribution inhomogeneity may present problems in sampling individual chocolate chip cookies, cans of sausages and beans, and croutons in a soup packet. The best strategy may often be to take a very large initial sampling quantity prior to
preliminary homogenization. Another approach is to take many replicate samples (20–200) for analysis to show individual unit variability. The various approaches yield different information that may meet different requirements. Pooling of several individual units may give better definition of the true mean of assay results (Figure 4). However, individual unit variation may better reflect single-serving variability for the consumer. The example of β-carotene content in canned stew in Figure 4 is a reflection of statistical sampling of units containing relatively few, large particles of carrots in a small discrete sampling bulk, from a large population. By pooling 12 cans together for assay, the manufacturer is able to meet specifications for vitamin A content using less of the ingredient, simply by the reduction of the RSD.

Often the analyst has little influence over the taking of the sample. Ideally the analyst should appraise the problem and take the samples personally. Failing that, the analyst should brief the sampler as to appropriate methods. An instance of such difficulty concerned an untrained sampler assigned to study traditional indigenous foods of Australian Aboriginals. He was an untrained sampler assigned to study traditional indigenous foods of Australian Aboriginals. He was

Several workers have recently reconsidered homogenization methods, conventional and otherwise, applied to foods. For assays using test portions of 1 g or more, several conventional methods prove satisfactory with compatible matrices. Many method–sample category combinations prove to be incompatible, some unexpectedly so. Conventional techniques usually operate by the mechanisms on cutting and shearing for samples of wet consistency, and shearing and impact for dry samples. Weaknesses of these techniques include the reliance on the inertia of the supporting fluid, or surrounding particles, as the “anvil” for the grinding action. Examples of failure of these methods include the persistence of corn kernel skins and long meat fibers. For techniques such as hammer milling the serrated body of the grinder serves this purpose. The CO₂ milling technique uses dry ice as inert mass particles, which also serve to embrittle the food particle. The liquid N₂ milling technique similarly uses cryogenic embrittlement, and uses a metal–metal impacting action. For assays using smaller test portions or requiring stringent homogeneity of very heterogeneous foods, the cryogenic treatments prove well worth the extra effort after a conventional pretreatment and freeze-drying. This dual treatment reduces particle sizes to below 60 µm (97% below 10 µm) for one of the most difficult matrices (muesli bars) with sufficient mixing to take reproducible test portions of 1 mg. The average RSD of microcombustion protein assays for a range of foods was 1.33%, performed on test portions of 2–5 mg. The number of particles included in such a 2-mg test portion following N₂ milling is approximately 1 × 10⁵.

The required size of the test portion and the sample’s characteristics will dictate the degree and type of obvious limitations of nutritional assays on such poor samples, the data are nevertheless at least indicative and still useful in this context, where previously nothing was known. Investment in an expert sampler can clearly boost the value of analytical data.

3 HOMOGENIZATION OF SAMPLES

The classical wet chemistry methods of analysis held sway for decades. These rarely used test portions less than 1 g, and the measurement precision was variable. Hence the conventional methods of homogenization usually provided adequate test portion sampling. More recently, with the development of analytical instrumentation, detection limits and test portions decreased dramatically, while sensitivity to contaminants and artifacts increased. Simultaneously, as matrices became more diverse, so did the diversity of analytes of interest. The need arose to review existing methods for homogenization and develop new techniques to meet the new demands adequately.

For assays using test portions of 1 g or more, several conventional methods prove satisfactory with compatible matrices. Many method–sample category combinations prove to be incompatible, some unexpectedly so. Conventional techniques usually operate by the mechanisms on cutting and shearing for samples of wet consistency, and shearing and impact for dry samples. Weaknesses of these techniques include the reliance on the inertia of the supporting fluid, or surrounding particles, as the “anvil” for the grinding action. Examples of failure of these methods include the persistence of corn kernel skins and long meat fibers. For techniques such as hammer milling the serrated body of the grinder serves this purpose. The CO₂ milling technique uses dry ice as inert mass particles, which also serve to embrittle the food particle. The liquid N₂ milling technique similarly uses cryogenic embrittlement, and uses a metal–metal impacting action. For assays using smaller test portions or requiring stringent homogeneity of very heterogeneous foods, the cryogenic treatments prove well worth the extra effort after a conventional pretreatment and freeze-drying. This dual treatment reduces particle sizes to below 60 µm (97% below 10 µm) for one of the most difficult matrices (muesli bars) with sufficient mixing to take reproducible test portions of 1 mg. The average RSD of microcombustion protein assays for a range of foods was 1.33%, performed on test portions of 2–5 mg. The number of particles included in such a 2-mg test portion following N₂ milling is approximately 1 × 10⁵.

The required size of the test portion and the sample’s characteristics will dictate the degree and type of

Recommended daily allowance (%)
homogenization required. If several different assays are to be performed on a sample, then whichever has the most stringent requirements will often dictate the homogenization requirements. Experience shows that it is often prudent to use two or more homogenization techniques sequentially. It may be desirable to split the sample after an initial wet-basis homogenization treatment, analyzing the first part for labile vitamins directly, and further rigorous homogenizing after freeze-drying before subjecting the second part to other analysis. A generalized example scheme for homogenization of samples for nutritional analysis is shown in Figure 5. This scheme includes approximations for quantities and particle sizes at each stage, and what types of assays are amenable to the products of each stage. However, it must be reiterated that each sample will have different characteristics which will require different homogenization treatments. Table 2 provides a summary of example assays and the consequences of using three example homogenization treatments. The main conclusion that should be drawn is that each sample should be homogenized by methods that have proven effectiveness with the particular matrix, either from experience, from the literature, or by experiment, to a degree that meets the test portion requirements and other facets of the assay procedures. This must be confirmed by the precision of replicate assays, blanks, and recoveries.

### 3.1 Reduction of Particle Size

There are two functions of homogenization: reduction of particle size and mixing. Reduction of particle size involves cutting, shattering, and shearing. The various homogenization devices achieve these in different ways to differing degrees. This necessitates a judicious choice of homogenization methods that have demonstrated applicability for use on particular matrices. The efficacy of a method may be observed by microscopic examination of homogenized samples.

or sieving of the product. The importance of particle size reduction is intuitive; the smaller the particles, the greater is the number of particles that will be included in a given test portion, hence the greater is the probability of sampling of more parts of the original bulk. Quantifying this statistical notion is more difficult. A simplified treatment with graphed relationships is recommended reading. The standard deviation (SD) plot in Figure 6 clearly shows the improvement in precision that results from particle size reduction. For reasonable precision in assaying a complex food, the sample should be ground sufficiently such that the smallest test portion should contain at least 500 particles of the least common ingredient.

Apart from the aspect of test portion sampling, particle size may influence other facets of the analytical procedure, where surface area and/or particle radius are critical to reagent exposure and penetration. Hence the degree of particle size reduction may affect both the accuracy and the precision of the analysis (Table 2), in ways that may not be readily revealed by recovery data. A typical case is the accessibility of the food matrix to enzymatic digestion. The efficiency of enzymatic digestion is proportional to the surface area (or degree of homogenization) of the food substrate, that is, inversely proportional to particle size (radius). Large particle size may inhibit enzyme access to the whole of the food, or specific portions may be encapsulated and not be available for subsequent extraction; such problems have been encountered in thiamine, lipid, moisture, and dietary fiber analysis. Efficient thiamine extractions were only possible after digestion of finely homogenized foods. In the second example, digestion of a well homogenized substrate was required for complete release of lipids. Efficient solvent extraction was found to be possible only with small particle radius (Figure 6). However, if some foods were too finely ground (with a very large reactive surface area), problems with emulsion formation hampered the efficiency of the subsequent liquid–liquid extraction. Moisture determinations are similarly affected by large particle size. Large-radius particles often fail to yield water quantitatively during the procedure, as the innermost molecules are trapped by the depth of surrounding material. Moisture–time curves for such samples are shallow and poorly defined, and do not reach a recognizable plateau. In contrast, Englyst dietary fiber determinations on poorly homogenized samples give spuriously high results owing to the incorporation of undigested starch in the fiber fractions. Analysis of total dietary fiber by the AOAC method has different problems: if the sample is too finely ground then there is the risk of low results through losing fiber through the 90-µm porosity filter, even with the use of filter aids; if the sample is too coarse, then there will be high results from insufficient enzymatic digestion of other components, and a loss of precision from poorer test portion sampling of larger particles (Table 2).

3.2 Mixing of Powders

Particle size reduction helps to improve sampling at the test portion by increasing the number of particles sampled per test portion, but to achieve the full gain in accuracy and precision the sample particles must also be thoroughly mixed so the test portion includes a random selection of the different particles. Mixing is not easy – ask anyone who has attempted to blend home-made muesli thoroughly enough to prevent children from segregating the mix to maximize their favourite ingredient content!

Most sampling and homogenization processes for foods lead to powdered samples. Simple observation of powders leads to the definition of two broad categories: free flowing and cohesive. The distinct properties of each lead to important consequences for the analysis of test portions.

Free-flowing powders, such as rice or coarse sands, flow smoothly, have a non-dusty appearance, and tend not to adhere to container walls. In broad terms, particle size for free flow needs to be above 50 µm, given

![Figure 6](image-url)
to overcome cohesive forces, to break up and disperse and the inclusion of all the sample. Shearing is necessary wet-basis food samples. Many of the mixing properties of cohesive powders to poor mobility, is slower and is a more intensive pro-

oh the structure preventing classification. Therefore, any induced motion will lead to classification and segregation. The muesli example clearly falls into this category. Segregation mechanisms include projection, percolation, and elutriation. Coarse particles, by virtue of momentum, are projected further than finer particles. Smaller, denser particles have a greater ability and mobility to percolate through a loose mass of particles. Percolation may take place when moving down an incline, rolling and tumbling, pouring into a pile, or when subject to vibration. Elutriation is the loss of fines as dust. This commonly occurs when filling a container, where the displacement air blows dust out of the mixture, or when stirring or mixing in an open vessel. The use of jaw crushers and open milling techniques risk differential losses of fines. This loss of fines may be critical to analysis, as the composition of the dusts often differs markedly from that of the coarser particles. For example, dust in peanuts may be disproportionately rich in mycotoxins. The counters to these drawbacks of flowable powders are to reduce particle size by homogenization into a cohesive powder, or to ensure that any mixing is active, not passive. Mixing should involve active displacement of particles rather than allow them to choose their own paths. A rolling, tumbling mixer gives individual particles freedom to unmix and is undesirable, while a paddle mixer pushes and relocates groups of particles and is preferred.

Cohesive powders, such as flour, have an erratic stick-slip flow, are often dusty, and stick to container walls. A smaller particle size (<50 µm) by nature enhances the potential for mixing to meet test portion precision requirements. Furthermore, the cohesive structure inhibits segregation. Cohesive powders lack mobility as light individual particles are held in a structure and cannot easily move independently. Hence mixing tends to behave irreversibly, the structure preventing classification. Thorough mixing of a cohesive powder is more difficult owing to poor mobility, is slower and is a more intensive process. Many of the mixing properties of cohesive powders are shared with thick fluids and muds, typical of many wet-basis food samples.

Mixing needs attention in two areas: adequate shearing and the inclusion of all the sample. Shearing is necessary to overcome cohesive forces, to break up and disperse aggregates into the mixture: it is necessary repeatedly to break individual particles free from their structuring neighbors. For some powders gentle rolling and breaking of a tumbling mixer may cause sufficient restructuring. For more cohesive aggregates, it may be necessary to put in more energy in the form of high-speed impactors to create a high shear zone in the mixer. However, for sensitive matrices or analytes, care is required to avoid overheating the mixture either locally or as a whole. The second area of attention is to ensure the inclusion of the whole sample in the mixing process. The cohesion of finer powders lends them to be held up in dead spaces in the mixer and be isolated from the mixing action. Efficient scraping and sweeping of the entire mixing volume are essential.

There are several means that may prevent adequate mixing of foods: classification, agglomeration, and phase separation. Causes include differentiated particle sizes and shapes, surface adhesivity, electrostatic charging, disruption of stable structures maintaining surface tension, destruction of encapsulating structures, and various hydrophobic–hydrophilic interactions. Typical practical food examples include oil separation in finely ground nuts and classification of whole grain flour. Samples of brans and flours circulated for dietary fiber collaboration were found impossible to mix; the only means of foiling the classification of these flowable powders was to grind the samples further into cohesive powders. One common means of inducing classification error is the use of a vibrating spatula. This device should only be used for pure compounds. Mixing may be thwarted by the presence of a few large particles, especially if they contain the analyte of interest. Such a mixture needs to be reground to eliminate the large particles.

One may avoid such problems by selecting appropriate homogenization methods through experience and learning, but just as often by intelligent trial and error experimentation. The CO₂ Bamix homogenization method, for example, usually produces a powder with particle size around 100 µm, yet is usually cohesive in mixing properties. The shearing action of this technique tends to produce irregular elongated particles, and biological particles are often adherent, giving cohesive properties. The cohesion of the sample–CO₂ mixture requires systematic shaking and occasional scraping of the assembly during grinding to ensure inclusion of “dead” pockets. Mechanical mortar and pestle grinding similarly requires regular scraping, additional to that provided by the mechanical scraper. This method is very successful on some samples, but is poor for fatty foods where phase separation becomes a problem.

### 3.3 Evaluation of Homogenization

Mixing may be more difficult to examine than particle size reduction. Experience suggests that visual inspection
of color and texture is very useful, but not necessarily rigorous, especially in the case of a sample consisting of components of similar appearance. The combined effect of reduction and mixing may be examined by performing assays on replicate test portions. For this examination it may be prudent in some circumstances to run simple, cheap assays rather than to use the actual target assay. The use of an assay more sensitive to variation than the target assay may be warranted. However, for a complex mixture, the confirmation of adequate randomization of one ingredient does not necessarily ensure that other components are mixed. It may often be safer to carry out separate statistical analyses for at least the key different types of analytes associated with different ingredients.

Another method of potential value is statistical image analysis of the homogenized test portions under a microscope. The determination of particle size distribution is relatively straightforward. It may be necessary to color-label some components prior to treatment to aid differentiation of the constituent particles, and/or observe under various wavelengths. A simple example is the addition of iodine to differentiate starch particles in a light-colored mixture.

The nature of the components, in addition to homogenization, of a sample can be critical to the precision of a given test portion. Figure 7(a) and (b) show huge variations in theoretical curves for simple mixtures; the case of aflatoxins in peanuts has already been mentioned. Fortunately, most recommended homogenization techniques are found simultaneously to reduce particle size and mix samples both with at least reasonable efficiency.

4 SAMPLE PREPARATION

Sample preparation includes any operation performed to the test portion prior to the analytical measurement: storage, preservation, weighing, dilution, cleanup, extraction, digestion, purification, separation, derivatization, etc. Descriptions of these are usually included in publications, although they frequently lack background information, finer practical detail, or rigorous theoretical or practical error analysis.

4.1 Separation of Portions

Careful thought and often some background research are required to decide what parts of the sample are to be analyzed. For example, ought the surface scum and
sediment from a river sample be included in a digest for heavy metals – will the water piped by users include these fractions? Is fresh produce to be washed prior to pesticide analysis? If so, how? What constitutes the "edible portion" for a food sample? Examples of such separations include removal of outer leaves, peels, and pips from fresh fruits and vegetables, removal of bones and trimming of excess fat from meat, exclusion of brines from canned vegetables, but inclusion of liquid from canned fruit. Many such choices are subject to debate, such as the inclusion or otherwise of seeds in a sample of blackberry jam. It may be desirable to analyze both portions. In any case, it is standard practice to weigh the separate portions, analogous to the determination of moisture when drying a sample.

4.2 Preparing the Samples

Several workers have emphasized that for nutritional evaluation of food it is desirable to prepare the sample in the same way as it is commonly consumed prior to analysis. What are the customary methods and times of cooking of meals? What constitutes complete preparation of powdered soups and hot beverages? An example of inappropriate preparation is the analysis of such beverages for vitamins B₁ and C, where the assay of the beverage powder was assumed to be the measure of dietary intake. In reality, these vitamins degrade significantly when the powders are stirred into boiling water, especially if the water has been sterilized by chlorine or iodine agents, as is usual practice in this context. Vitamins in cooked foods may be reduced by as much as 80% when compared with the raw ingredient vegetables and meats. Food held for serving in Bain-marie suffers further losses. When bread is baked, 30% of thiamine is lost; if alkaline baking powder is used, the loss can increase to 80%.

4.3 Storage of Samples

Storage and identification of samples require meticulous attention and control. Analyzing the wrong samples is worse than any error generated by sampling, homogenization, preparation, or assay technique! Labeling of samples and all tubes, glassware, and containers used in their analysis must be meticulous, consistent, and unambiguous. The sample trail ought to be auditable at any time. The identification markings should endure any treatment (for example by solvent, microwave digestion, steam bath, freezing, or abrasion) encountered in the handling and analysis process. Storage conditions will be determined by the perishability of the sample/analyte, the delay before assay, and the duration of sample archival. Foods are generally frozen in sealed plastic after preliminary homogenization, or freeze-dried before and after further homogenization treatments and stored in desiccators. Tundra and ice core samples must be kept frozen and tightly sealed to slow deterioration and sublimation freeze burning. Geological drill core samples are best kept in as large pieces as possible in order to slow the degradation of unstable minerals from weathering processes. Change of moisture content, loss of dust fractions, pest attack, and oxidation are all such factors to minimize.

4.4 Weighing and Dilution

A practically universal step in the manipulation of the test portion is the weighing step. Fortunately, the precision of modern balances is commonly six significant figures or better. A judicious choice of balance can maintain this precision for a large range of test portion size, typically from 10 g down to 1 mg for most analyses. However, the analyst must ensure the operation is performed accurately: moisture variation of samples requires particular attention. Electrostatic charging may cause problems with dry samples, and may be eliminated through the use of ionizing tools, such as “antistatic guns” sold in audiophile stores for discharging vinyl records. These same errors must be considered when drying samples and determining moisture correction factors. Once dry, samples should be stored in a desiccator. Weighing of dry powders should occur with desiccant present in the weighing chamber of the balance; boats of silica gel are adequate for general use, phosphorus pentoxide being recommended for operations with more hygroscopic materials. Care is needed to avoid moisture adsorption problems with weigh containers and tools: it is prudent to store these in a desiccator, after drying in an oven.

Volumetric dilution is a virtually universal operation contributing to the sample manipulation error. Volumetric errors are inherently orders of magnitude greater than those for mass measurements. The practice of good basic laboratory techniques helps minimize the volume errors, as does to some degree the minimization of the number of volumetric steps. Volumetric errors include the delivery volume of gas chromatography (GC) syringes and the like. For vapor sampling, the size, pressure, equilibration time, and temperature of the vapor space are all critical. It may on occasion be prudent to weigh liquids to reduce the error contribution.

4.5 Digestion, Extraction, Cleanup Separation and Derivatization

Digestion, ashing, filtration, extraction, and derivatization should all be quantitative. Digestion efficiency may be enhanced, for example, by application of microwaves for HPLC, Kjeldahl nitrogen, and metal analysis, but only if sample integrity is maintained. Minor elements
may be determined after bomb calorimeter analysis in preference to open-oven dryashing and digestion.\textsuperscript{(44)} Confirmatory tests should be used in any doubtful cases. A typical simple test is the testing for residual starch with drops of iodine to confirm completion of amylase digestion.\textsuperscript{(30)}

The efficiency of extraction should be shown to be quantitative. Re-extraction of residues should be blank. Recovery of added spikes should be 100%, although this does not conclusively mean that the (bound) sample analyte is necessarily fully extracted. Better assurance may be achieved by the use of two independent methods or the use of standard reference materials. As intimated earlier, the degree of homogenization (particle size) may influence the efficiency of extraction to a greater\textsuperscript{(Figure 6)} or lesser\textsuperscript{(45)} degree. Recent developments in chromatographic analysis include the use of supercritical fluid extraction (SFE).\textsuperscript{(46–48)} The use of CO\textsubscript{2} reduces the potential for contamination and eliminates the problems associated with toxic solvents. Another novel cleanup method is the use of dialysis to remove all but small molecules prior to chromatography.\textsuperscript{(49)} Large molecules may also be digested by enzyme treatment, e.g. prior to amino acid\textsuperscript{(50)} or nitrate analysis.\textsuperscript{(51)}

The methods of ensuring good recoveries while using solid-phase absorption columns prior to liquid chromatography are straightforward. The use of preconcentration methods in GC\textsuperscript{(52)} can be fraught with complications of volatility differences, reactivity, and adsorption. These issues are generally adequately discussed in methodology papers alongside chromatography details.

### 4.6 Deterioration and Contamination

Degradation of the sample and analyte integrity may take place at any stage, from the taking, transport, and storage of the sample, drying, homogenization, and sample preparation to the analysis of the test solution. Addition of contaminants, exposure of samples to heat, warmth (microbiological activity), moisture, oxygen, visible and ultraviolet light, and reagent fumes can all compromise accuracy. These problems are considerable in vitamin analysis, e.g. riboflavin is sensitive to ultraviolet light. Vitamins A, B\textsubscript{6}, D, and E and folic acid are light sensitive. Laboratory manipulations are usually performed using tinted glassware and preferably in the dark.\textsuperscript{(28,53,54)} Plant tocopherols are sensitive to oxidation. Losses during sample preparation are minimized by pyrogallol addition.\textsuperscript{(55)}

Ascorbic acid is particularly sensitive to oxidation, promoted by atmospheric exposure, heat, or high pH. Analysis schemes aim to reduce manipulation and turnaround time to an absolute minimum, making use of various stabilizing agents. A number of methods use metaphosphoric acid addition at the homogenization stage. The 10-fold variation in ascorbic acid found in \textit{Terminalia ferdinandiana}, a native Australian plum rich in this vitamin,\textsuperscript{(19)} is partly due to degradation during sample transit. Furthermore, contamination by traces of copper catalyzes oxidation.

Contamination of samples can occur at any stage of analysis from contact with unsuitable container surfaces, lids or seams, reagents, ingress to open containers, carryover from past samples, diluents, and preservatives. Polytetrafluoroethylene (PTFE), polypropylene, glass, and stainless steel are most commonly used for laboratory ware, but contact with other materials may be unavoidable. However, even glass or stainless steel may leach boron, silica, sodium, chromium, iron, nickel, and molybdenum under certain conditions.

Metal contamination, particularly by trace elements, is a common laboratory problem. Trace metals may be of interest from a nutrient point of view or as environmental contaminants. Many laboratories redistil acids on-site, in addition to using elaborate water purifiers. Recent work quantified the metal increment of using laboratory blenders.\textsuperscript{(56,57)} This increment is able to be reduced by chemical treatment of the blender surfaces.\textsuperscript{(57)} Another approach is to design\textsuperscript{(58)} or seek out homogenization devices with inert working surfaces. For laboratories dedicated to trace metal work, a clean room is a good investment to minimize laboratory environmental contamination.\textsuperscript{(59)} High purity, smooth surfaces, filtered ventilation, and positive pressure airlocks are typical features. Precautions may include the use of overclothing and hair confinement and strict “hygiene” practices analogous to those used in infectious bacteriology. Care is taken to avoid transfers via all contact surfaces, hands and implements, air, and dust. Such practices are not confined to metal analysis, but extend to any trace and environmental analysis where contamination of the samples or personnel is a potential hazard. Introduction of metal contamination may be serious beyond the simple raising of metal content. The presence of metal may promote degradation reactions, compromising sample integrity, as mentioned above, but may also interfere with extraction, cleanup, and enzymatic digestion steps of sample preparation procedures.

Contaminants may be introduced by reagents. Method development for enzymatic digestive release of lipids\textsuperscript{(29)} revealed that several commercial enzyme preparations contain unacceptably significant amounts of ether-extractable contaminants, adding artifact to the total determination of fat.

Contamination and the potential complications in sample preparation procedures are highlighted by the GC of alditol acetates in the Englyst dietary fiber determination. Plasticizers may contaminate food.
samples at literally any point from the farm to the chromatograph. Pure samples of ubiquitous plasticizer contaminants chromatograph at similar times to some of the analytes, but are be resolvable from analyte peaks by use of capillary columns. However, exposing plasticizers to the derivatization procedure used to form alditol acetates yields multiple and broad peaks that interfere with the analytes (Figure 8a and b). This is an additional artifact caused by the sample preparation technique fundamental to the analysis. Thus one eliminates leachable plastics [such as poly(vinyl chloride)] from the analytical procedure. Sample preparation artifacts have similarly been observed in fatty acid methyl ester analysis, where compounds synthesized by the derivatization interfere with the GC peaks of interest. A novel approach to derivatization of fatty acid mixtures is to react the sample with reagent in the GC injection port, thus eliminating bench chemistry and attendant problems of sample contamination, errors, and limited control of reaction conditions. A monograph describes such analytical artifacts, with considerable attention to problems with gas chromatography/mass spectrometry (GC/MS), a technique widely regarded as definitive with respect to analyte specificity.

Sample Preparation, Headspace Techniques

Alain Chaintreau*
Nestlé Research Centre, Lausanne, Switzerland

1 Introduction

Among sample preparation techniques used prior to gas chromatography (GC), headspace sampling (HS) offers many advantages as it only collects vapors that are directly compatible with GC. The main variants are: (1) collection of a fraction of the HS (static headspace, SHS), (2) gas stripping of volatiles from a solution and subsequent trapping in an adsorbent (purge and trap headspace, P&THS), (3) collection and trapping of volatiles from a whole HS in equilibrium with a liquid (static and trapped headspace, S&THS), (4) partition of volatiles between a sample, its HS, and an adsorbent fiber (headspace solid-phase microextraction (HSSPME)). For each one, a design and some guidelines for qualitative and quantitative use are given, as well as the equation giving the theoretical recovery. Performances are compared between HS techniques and others such as simultaneous distillation extraction (SDE).

A special section is devoted to the timesaving hyphenation of HS to detectors without chromatographic separation like HS-sensor array and headspace sampling mass spectrometry (HSSMS).

Main HS applications in various areas (food, environment, health and biosciences) since the late 1980s are illustrated. In addition, HS appears to be a unique tool to measure thermodynamical constants of volatiles characterizing their partitioning between phases and their interactions with a nonvolatile matrix.

1 INTRODUCTION

Discussing HS techniques in a sample preparation article is something of a paradox as this methodology needs little sample preparation, if any at all! As GC is only suitable for vaporizable components, these latter must normally be isolated from nonvolatile compounds of the matrix by an appropriate technique prior to injection (extraction, distillation, etc.). In contrast HS only samples vapors which are directly compatible with the GC process.

HS using a gas syringe is one of the oldest injection techniques in GC (see section 2.1.1). This article mostly deals with the headspace sampling gas chromatography (HSGC) hyphenation (section 2) because it is the subject of the majority of published papers. However, there is increasing interest in direct coupling of HS to detectors enabling the specific monitoring of a given compound in a mixture without preseparation of its constituents. This timesaving approach is also considered hereafter (section 3). At the end of this article, the use of HSGC as a unique technique to measure some thermodynamic properties of volatiles that are difficult to obtain by other means is considered (section 6).

2 HYPHENATION TO GAS CHROMATOGRAPHY

2.1 Static Headspace

Readers interested in an extensive review of SHS should refer to Kolb and Ettre’s book.\(^{(1)}\)

2.1.1 Design and Principle

2.1.1.1 Manual Injection  
The most simple SHS injection mode only requires a gas-tight syringe and a closed vial containing the liquid or solid sample. Both are kept in a thermostated oven to equilibrate their temperature prior to withdrawing the headspace. The usual split/splitless injector may be used. Detailed procedures exist for volatiles in polymers and flavors.\(^{(2)}\)

2.1.1.2 Autosampler  
To overcome reproducibility problems that are inherent in manual injection (thermostatization, control of the pressure within the vial and the syringe, injection duration, etc.), SHS autosamplers were developed early on. The vapor phase may be transferred from the vial to the column in two different ways. In the first,\(^{(3)}\) a vacuum is applied to a gas loop connected to the vial by a needle. After filling the loop, its content is pushed by the carrier gas onto the column by switching a multiport valve (Figure 1). In the second,\(^{(1)}\) the vial is pressurized by the carrier gas, then the carrier gas flow is stopped to release the vial pressure directly onto the GC column (Figure 2).

In both cases, there is a modification of the HS pressure and only a fraction of the gas phase is collected. In commercial autosamplers, the vial as well as the transfer line are thermostated to avoid any condensation. The pressure and the times of equilibration and sampling are electronically controlled to ensure good reproducibility.

2.1.2 Theoretical Recovery

The gas-to-liquid partition coefficient is defined as the ratio of the concentration in air \(C_g\) to that in the liquid \(C_l\), Equation (1):

\[
k_{gl} = \frac{C_g}{C_l}
\]

If a fraction \(f\) of the HS volume is transferred onto the GC column, the recovery \(\rho_i\) of a volatile is given by

\[
\rho_i = f \cdot k_{gl}
\]
Equation (2):\(^{(1)}\)

\[
\rho_i = \frac{f k_{gl} V_g}{V_i + k_{gl} V_g}
\]

where \(V_g\) is volume of HS and \(V_i\) is volume of liquid.

From Equation (2) the injected amount strongly depends on the partition coefficient \(k_{gl}\), the fraction of the collected gas volume \(f\), and the ratio of phase volumes. Maximizing \(V_g/V_i\) maximizes \(\rho_i\), while \(f\) is fixed by the hardware to less than 1. Alternatively, a higher temperature improves the sensitivity as \(k_{gl}\) increases with this parameter. However, for aqueous samples this possibility is limited by the enhancement of the moisture level which disturbs the chromatography.

2.1.3 Use for Quantitation

Usual GC quantitation methods, internal normalization and internal standardization, are theoretically applicable to SHS/GC. The former requires reconstitution of a mixture containing all constituents of the sample (all volatiles diluted in the same matrix). In practice only fully gaseous samples that have a relatively simple composition can be analyzed in SHS/GC by internal normalization.\(^{(1)}\)

Internal standardization applied to SHS also suffers from some limitations. The added internal standard should have the same air-to-matrix partition coefficient as the target compounds, otherwise partition coefficients of the internal standard and target volatiles must be accurately known. In addition, the matrix used to dilute the standards must be identical to that of the sample, without containing target compounds or the internal standard. The same requirements for the matrix and partition coefficients remain valid for a third method, external standardization. The removal of volatiles from the liquid sample has been proposed so that the “deodorized” liquid can be used as a solvent for the preparation of standard solutions.\(^{(4)}\)

Because of the above mentioned limitations, two other techniques are generally preferred when a SHS sampling is performed: standard addition, and multiple headspace extraction (MHE). Standard addition overcomes the problem of the matrix choice because known amounts of the target compound are added to the sample itself. Details of an example of quantitation by standard addition are given in section 2.3.3.

MHE eliminates the matrix problem, as a total extraction of the analyte is simulated. Therefore it has often been applied to very complex matrices such as those that are found in the environment (e.g. soils). A series of pressurizations with the carrier gas, and GC injections of the HS are performed using the same sample contained in

---

**Figure 3** Chromatogram from a nine-step MHE determination of cyclohexanone (CHX) in a contaminated soil sample, and regression lines using a standard (■) and the sample (●). (Reproduced from Milana et al., *J. Chromatogr.*, 552, 205–211. Copyright 1991 with permission of Elsevier Science.)

---
a closed vial. After each injection, volatiles migrate from the matrix to the gas phase to re-establish a new partition between the phases. Amounts of volatile extracted into the HS decrease according to Equation (3):

\[
\ln(A_i) = -k(n-1) + \ln(A_1)
\]

where \(A_i\) is the area of the analyte in the \(i\)th HS injection, \(n\) is the number of extractions and \(A_1\) is the area of the analyte in the first injection.

Consequently, the area \(A_T\) corresponding to the total amount originally present in the sample is the sum of areas of all extracted amounts, Equation (4):

\[
A_T = \sum (A_i) = \frac{A_1}{1 - e^{-k}}
\]

In practice a few extraction steps are sufficient to obtain \(k\) from Equation (3), by applying a regression calculation (Figure 3). The calibration may be performed by external standardization using the same volatile in a different matrix, or by internal standardization with another volatile, submitted to the same MHE process.\(^6\)

In both cases, the difference of volatility inherent to the different matrices or compounds does not influence the \(A_T\) value because this area represents the whole quantity present in the matrix. Recoveries in the 90–110% range are usually observed with relative standard deviations often less than 15%.\(^5-7\)

2.2 Purge and Trap Headspace

2.2.1 Design and Principle

To collect a large volume of HS, and subsequently a greater amount of its volatiles than those present at equilibrium, a liquid sample may be continuously stripped by a flow of pure and inert gas. Volatiles must then be trapped from the gas flow.\(^9\) This can be achieved in three ways:

1. They can be dissolved in a solvent reflux and GC injected.\(^10\)
2. They may be cryofocused in a cold loop,\(^11\) or on the beginning of the GC-column itself.\(^12\)
3. Many automated systems trap them in an adsorbent (graphite, Tenax,\(^6\) Porapak,\(^6\) etc.), from which they are either thermally desorbed,\(^9\) or eluted with a solvent.\(^13\) Figure 4 shows the principle of a usual automated P&THS system. As a variant for solid materials, a piece of the sample can be put directly into a thermal desorber under a flow of gas. Volatiles released by the controlled heating are trapped and then GC injected.\(^14\) To analyze plants, only a small amount (1–40 mg) of the raw material is required.

Desorption from a trap may be achieved in two ways. The adsorbant can be rinsed off with a small amount of solvent (diethyl ether, CS\(_2\), etc.) that is then GC injected.\(^15–17\) As the solvent choice sometimes gives rise to selective desorption, recoveries must be checked.\(^18\) The second way is heating of the trap. This alternative is the most frequently used as numerous automated thermal desorbers are now commercially available. Thermolabile components such as terpenes are advantageously desorbed with a solvent to avoid artifacts.\(^17\) However, adsorbant pretreatment with an antioxidant and a buffer has been said to prevent degradation of these fragile compounds during thermal desorption.\(^19\)

Most P&T applications have been developed for aqueous samples because the solvent must be nonvolatile or it must not be trapped on the adsorbent. Water fits the second requirement. However, any other solvent answering these conditions could be used, as well as solid matrices.

In a variant, the purging and trapping systems are connected in a closed loop assembly owing to a pump circulating the stripping gas in the loop.\(^20–22\) This method is claimed to perform significant extractions of furanol and maltol, scarcely strippable aroma compounds.\(^21\)

2.2.2 Theoretical Recovery

The recovery of a given volatile stripped from water by the gas flow is given by:\(^23\)

\[
\rho_i = 1 - e^{-\frac{k_i F_i}{V_T + V_i}}
\]

Figure 4 Scheme of an automated P&THS injector. (Reproduced with permission of Tekmar-Dohrmann, USA.)
where $F$ is the flow of stripping gas, $t$ is the duration of the stripping, $V_g$ is the void volume of the sampling cell, $V_1$ is the volume of the solution, and $k_{gl}$ is the gas-to-liquid partition coefficient.

If $k_{gl} V_g$ is negligible (small void volume of the cell and/or small $k_{gl}$ values), Equation (5) can be simplified: \(^{(23)}\)

$$\rho_i = 1 - e^{-k_{gl} F / V_1}$$  \hspace{1cm} (6)

Equation (6) shows that, for a given $k_{gl}$ value, the sensitivity is better than when using SHS because the total gas volume ($Ft$) may be much greater. Therefore the GC profile obtained after P&THS is not representative of the HS composition at equilibrium. For an infinite GC profile obtained after P&THS is not representative.

Equation (6) shows that, for a given $k_{gl}$ value, the sensitivity is better than when using SHS because the total gas volume ($Ft$) may be much greater. Therefore the GC profile obtained after P&THS is not representative of the HS composition at equilibrium. For an infinite GC profile obtained after P&THS is not representative of the HS composition at equilibrium. Therefore, P&THS may be used to investigate volatile species whose volatility is sufficient for the purge and trap cycle, and for which a suitable trapping procedure is available, otherwise losses must be expected. \(^{(29,31)}\)

Breakthrough volumes of many volatiles in various adsorbents have been published. \(^{(20,31)}\) Very efficient adsorbents such as active charcoal may not quantitatively release trapped components. \(^{(32)}\) The desorption step may give rise to artifact formation. For instance microwave heating of graphite traps seems to yield benzene derivatives systematically. \(^{(33)}\) Therefore, blank experiments must be run, using the same system and, possibly, the same matrix (at least pure water for aqueous samples).

2.2.4 Use for Quantitation

In many cases, quantitation using P&THS is not simple because several parameters influence the experiment. Recoveries of volatiles vary according to temperature and gas flow fluctuations, stripping duration and different air-to-matrix partition coefficients of components. This can be partially overcome by electronically controlled purge and trap autosamplers (time, flow and temperature regulation). However, the variability of $k_{gl}$ values between solutes of a sample is sometimes forgotten by analysts.

2.2.4.1 External Standardization

Some authors calibrate by injecting known standard amounts either into the trap using a syringe, \(^{(34)}\) or into splitless injectors without changing other chromatographic conditions. \(^{(17)}\) Such a procedure does not take into account the stripping efficiencies of the analyte, which must be evaluated separately to correct quantities found using the calibration curve. \(^{(34)}\) The calibration curve is also often established by submitting model solutions containing standards to the same purge and trap conditions as the target sample. \(^{(35)}\) This requires either that recoveries are quantitative or that identical efficiency is obtained for the quantitated sample and standard solutions. This last condition is only fulfilled if standard solutions are prepared in the same matrix as the sample. This matrix must obviously not contain any of the compounds to be quantified.

2.2.4.2 Internal Standardization

The sample is spiked with a standard prior to stripping. It assumes that standard and target compounds are fully recovered or that they possess identical air-to-sample partition coefficients. Although it is rarely checked, internal standardization is often used, with the risks inherent in this approximation. \(^{(36,37)}\) The correction of results with recoveries estimated in a different matrix from the sample does not seem satisfactory. \(^{(16)}\)

MHE has also been used, with some modifications of the static MHE model to take into account the purge process. \(^{(38)}\)

2.2.4.3 Standard Addition

According to Equations (5) or (6) recoveries are independent of the concentration. Therefore, added or pre-existent amounts of
the target compound are recovered in identical ratios and a calibration curve may be drawn. The procedure is similar to that used for SHS and S&THS.

2.2.4.4 Labeled Standards

The use of an isotopomer of the target compound allows its accurate quantitation when it is represented by a very small peak included in a complex chromatogram. The problem of purge and trap recovery efficiency does not intervene because both labeled and unlabeled compounds are assumed to behave similarly.

2.3 Static and Trapped Headspace

2.3.1 Design and Principle

The injection of large gas volumes exceeds capacities of classical injectors used in SHS and the measurement of the total gas volume is not accurate in P&THS. S&THS combines advantages of both techniques (Figure 5). Volatiles are equilibrated between the sample receptor and the HS chamber. When the piston is pressed, volatiles are evacuated through the transfer tube and trapped by the adsorbent. This latter is then transferred to a thermal desorber for injection onto the GC column.

2.3.2 Theoretical Recovery

The formula representing the recovery is similar to that of SHS, but the gas volume is greater and fully recovered, Equation (7):

$$\rho_i = \frac{k_{gl}V_g}{V_i + k_{gl}V_g}$$

where $V_g$ is the volume of headspace and $V_i$ is the volume of liquid.

For a given volatility, the sensitivity mainly depends on the gas volume $V_g$ which is only limited by the size of the cell. As for SHS, a temperature enhancement also increases $k_{gl}$ and then $\rho_i$.

2.3.3 Use for Quantitation

Two S&THS methods have been proposed for quantitation. The first one requires determination of air-to-liquid partition coefficients, using the same HS cell (see section 6.1). Then HS concentrations may be calculated from the initial concentration of aqueous calibration samples. Using the resulting curve, HS peak areas of the sample to be analyzed can be transformed into quantities. The coefficient of variation for the method was estimated to be 3.4% for 2-butanone. The MHE procedure is suitable to determine the concentration in the solution. No application of this first method has yet been published.

The second method uses the standard addition procedure. Known quantities of the target compound are added to the analyzed solution. The HS of the spiked samples is then collected by S&THS and injected. By determining the straight line representing peak areas as a function of the added standard concentrations, including the area of the compound without addition, the initial amount of the target compound is given by extrapolating the curve to zero area. The intercept with the abscissa represents its concentration (Figure 6). Applied to yogurt, recoveries were 87–114% and standard deviations less than 5.5%.

2.4 Solid-phase Microextraction Headspace

2.4.1 Design and Principle

Solid-phase microextraction (SPME) was proposed in 1990 as a rapid extraction technique from a liquid sample. In the original concept, a fiber coated with a bonded liquid phase is dipped into the liquid and then desorbed in the GC injector. It was observed that volatiles could also be extracted from the vapor phase by exposing the fiber to the HS of a sample contained in a closed vial (Figure 7). It has been shown that recoveries from the HS at equilibrium are often close to those from the liquid phase (see section 2.4.2). In addition HSSPME avoids polluting the fiber with nonvolatiles in the liquid.
When the term \(k_{fl}V_{fl}\) is small (e.g. pyridine: \(k_{fl} = 5.71 \times 10^{-4}\) at 25 °C, \(V_{fl} = V_{f} = 1\) mL), Equation (8) can be simplified as Equation (9):

\[
\rho_i = \frac{V_{fl}k_{fl}}{V_{fl}k_{fl} + V_{f}} \tag{9}
\]

which represents the recovery from a liquid sample. Therefore it must be pointed out that, in spite of its name, HSSPME is not representative of the headspace composition, but rather that it represents the direct partition between the fiber and the liquid.

If the sampling temperature rises, the extraction is faster, but the effect on the HS concentration at equilibrium depends on the compound. If \(k_{fl}\) is greater than 1 (exothermic partitioning into the fiber), increasing the temperature decreases \(k_{fl}\) and vice versa.\(^{41}\)

Equation (8) also shows that the sensitivity is improved by maximizing \(V_{f}/V_{fl}\) or minimizing \(V_{f}/V_{fl}\).

### 2.4.3 Use for Quantitation

SPME has been shown to be reproducible when experimental conditions are kept constant (stirring rate, temperature, sampling time).\(^{44}\) The time to reach the air/matrix equilibrium varies greatly according to the solute, the matrix and the fiber coating. For instance HS-fiber exposures of about 25 and 150 min were necessary for Dichlorvos and Napromide in water, respectively.\(^{45}\) This means that this time to equilibrium should always be determined prior to developing a quantitation method. However quantitation under nonequilibrium conditions has been proven to be feasible.\(^{46}\)

External standardization is the most common SPME quantitation method.\(^{47,48}\) The calibration solvent must obviously be identical to the sample one, without containing target components. Internal standardization is not easy because of recoveries varying with varying partitions of the internal standard and the target compounds. Its application to tobacco alkaloids was not found to be fully satisfactory.\(^{49}\) Standard addition overcomes matrix problems better by using the sample as the solvent.\(^{50}\) Best results are obtained with labeled standard and MS (mass spectrometry) detection.\(^{51}\)

### 2.5 Vacuum Headspace

The literature sometimes mentions as “vacuum headspace” sampling techniques involving the distillation of volatiles under high vacuum. These methods will not be mentioned in this article because, in the author’s opinion, they relate to distillation or steam-distillation, rather than to HS.
2.6 Membrane Techniques

2.6.1 Design and Principle

Pervaporation membranes may help HS and can be used in two ways:

- One side of the membrane is contacted with the liquid sample, while the second side is swept by the GC carrier gas flow (Figure 8).\(^{3,4}\) Volatile solutes permeate through the membrane and are conveyed to the GC column. They can be concentrated by interfacing the membrane device and the chromatograph with a microtrap. Aqueous benzene solutions may be quantitated in the 10–150 ppb range by external standardization.

- Membrane extraction with sorbent interface (MESI). Instead of contacting one of its sides with the liquid sample, the membrane separates the sample HS from the carrier gas flow which extracts volatiles passing across the hollow-fiber membrane.\(^{5}\) Quantitation by standard addition has been used.

2.7 In Situ Headspace Gas Chromatography

2.7.1 Design and Principle

In situ HS refers to the monitoring of volatiles emitted by a source as a function of time. A typical example is the release of odorants by a living plant over the day.\(^{56}\) This requires a noninvasive sampling technique such as trapping of volatiles from air by a trap, subsequent desorption and GC analysis. The emitter (e.g. a living flower) is enclosed in a HS chamber made of glass, Plexiglas\(^{39}\), or in a polyvinyl fluoride bag, connected to a pure air inlet (Figure 9). The gas exiting the chamber passes through a trap such as those described for P&THS. Recent systems use an array of several traps in parallel, into which the exiting air is successively admitted. Time programming of traps and other parameters (temperature, pressure, air humidity, etc.) are controlled by computer.\(^{57,58}\)

2.7.2 Quantitative Use

Obtaining real quantitative results by in situ HS may be hard because leaks are difficult to prevent (e.g. because of the difficulty of sealing a fragile stem passing through

---

**Figure 8** HS by permeation through a hollow-fiber membrane in conjunction with carrier gas stripping. FID, flame ionization detector. (Reproduced with permission of Wiley-VCH from J. High. Resolut. Chromatogr. Copyright 1996.\(^{33}\))

**Figure 9** Collection assembly for in situ HS analysis of volatiles emitted by a plant. (Reproduced with permission of Plenum Publishing Corp. from J. Chem. Ecol. Copyright 1994.\(^{57}\))
the chamber wall). In addition the incorporation of an internal standard to the emitter is not possible. Addition of the internal standard after solvent elution of the adsorbent has been mentioned.\(^{(57)}\)

### 2.8 General Remarks

#### 2.8.1 Sample Storage

When analyses cannot be performed close to the HS collection area, samples may need to be stored and transported to the laboratory. Several means have been proposed. Teflon\(^{®}\) or Tedlar\(^{®}\) bags are often used, but permeation of volatiles through the polymeric wall occurs and they are not recommended for long-term storage.\(^{(59)}\)

The air to be analyzed can be admitted into metallic canisters or glass bulbs previously evacuated to a low pressure.\(^{(30)}\) To avoid degradation of sulfur-containing constituents, the stainless steel wall can be coated with a bonded silica layer.\(^{(60)}\) For large volumes, the gas can be percolated through an adsorbent which only retains organic compounds (see section 2.2.3). Airtight tubes containing trapped volatiles may be stored up to 2 years.\(^{(61)}\)

#### 2.8.2 Salting Out

A usual means of increasing the volatility of organics in aqueous samples consists in the addition of salt. Recoveries of volatiles are normally greatly improved.\(^{(42,62–64)}\)

#### 2.8.3 Labeled Standards

With any HSGC technique the best way of calibrating for quantitation remains the use of an isotopomer of the target compound itself as the internal standard. This requires detection by MS.\(^{(65)}\)

### 3 DIRECT HYPHENATION TO A DETECTOR

Hyphenation of HS to GC exhibits a major drawback for some applications: it does not provide the analyst with real-time monitoring of the volatiles. Even automated systems described for in situ HS require an off-line trap desorption and a time-consuming GC elution. Therefore the direct hyphenation of HS to a detector has been studied. When the objective is to monitor one or several compounds in a mixture, selective detectors must be chosen.

#### 3.1 Sensor Array

This detection means has become very popular and is often improperly called an “electronic nose” because it mimics odor detection by the array of receptors in the nose. However its sensitivity and selectivity cannot be compared to those of the mammalian organ which is able to detect a component having an extremely low odor threshold in a complex mixture of less intense odorants (e.g. 18 ppb of 2,4,6-trichloroanisole in cork-tainted wine\(^{(65)}\)).

Semiconductor metal oxides, conductive polymers or quartz resonators have been used to build sensors. When volatile organic compounds (VOCs) are present in the sample’s HS, the sensor’s conductivity or resonance frequency changes according to the nature of the sensor’s material and the nature of the organic compounds.\(^{(66)}\)

Individual signals produced by the elements of the sensor array generate a response profile more or less characteristic of the detected odor. Although sensors exhibiting different selectivities may be used in the same array, this selectivity remains low. However, in spite of their limited ability to provide information about HS composition, sensor arrays can easily detect composition differences in the vapor phase, especially with the aid of chemometrics to treat raw data, such as principal component analysis (PCA).\(^{(67)}\)

Therefore sensors are most often used in quality assurance to classify global profiles of volatiles present in the gas phase, without giving information on its composition.\(^{(68)}\)

#### 3.2 Mass Spectrometer

##### 3.2.1 Chemical Sensor

Routine MS detectors have been directly hyphenated with HS autosamplers without any GC separation in between. These systems use an electronic impact ionization (70 eV) yielding a strong fragmentation. The resulting complex spectra are used as “fingerprints”. Therefore data treatment also requires chemometrics to extract relevant information.\(^{(25,69)}\)

##### 3.2.2 Proton-transfer Reaction Mass Spectrometry

This technique\(^{(70)}\) uses chemical ionization by H\(_3\)O\(^+\) ions which form MH\(^+\) quasimolecular ions with little fragmentation. In addition, H\(_3\)O\(^+\) does not react with the natural constituents of air. Therefore, since spectra of mixtures mainly contain quasimolecular ions of their constituents, following one of them becomes possible, as long as no isobaric ion interferes with that of the compound of interest. Consequently, monitoring the HS composition as a function of (real) time, or of any parameter that can be varied as a function of time, is feasible, with a quantitative signal. It is an alternative to in situ HSGC (section 2.7) with a lower selectivity and a quicker response.
FOOD

Resonance-enhanced multiphoton ionization, hyphenated to MS, also permits direct monitoring of the HS without previous separation. Laser excitation of the volatiles leads to specific ionization of a chemical class of compounds.\(^{(71)}\)

4 APPLICATIONS

Between 1987 and 1998, the Chemical Abstracts' compilation lists about 1070 papers related to the "headspace" keyword. This does not take into account publications using sensor arrays. Three main application areas of HS may be distinguished: (1) food, flavors and fragrances (34%); (2) environment (26%); (3) health and biosciences (21%). The remaining papers deal with method development, phase equilibrium, plastics and inorganic analysis. Only examples or review papers will be cited to illustrate each topic because references are too numerous to be exhaustive within the limits of this article.

4.1 Foods, Flavors, Fragrances, Essential Oils

4.1.1 Identification and Quantification of Flavor and Fragrance Constituents

Many articles and reviews have already been dedicated to the use of all HS techniques for the identification and quantification of flavors and fragrances.\(^{(36,72,73)}\) Because S&THS collects odorants that are in equilibrium with a given food, for example in its packaging, this sampling method was recently hyphenated to GC-olfactometry to determine aroma impact compounds.\(^{(40,74)}\) With the help of statistical tools (e.g. PCA) to treat HSGC results, some sample classification can be achieved according, for instance, to botanical varieties such as arabica/robusta coffees\(^{(75)}\) or grape vines.\(^{(42)}\)

4.1.2 Off-flavors

HS is a suitable technique for investigating off-flavors such as trichloroanisole which confers the cork taint on wine.\(^{(65)}\) It can be associated with GC-olfactometry to determine undesirable odorants by comparison with the aromagram of the nonaltered sample.\(^{(76)}\)

4.1.3 Food Process Monitoring

Maturing processes may need an objective evaluation in addition to sensory analysis. This is especially valuable for fermented foods such as dry ham\(^{(37)}\) or olives in brine.\(^{(77)}\) The thermal generation of an aroma, like that of roast coffee\(^{(78)}\) or process flavors,\(^{(79)}\) can also be monitored by HS.

4.1.4 Food Preservation

The quality and safety of industrial food products requires their shelf life and storage conditions to be determined.\(^{(80)}\) In this respect, lipid oxidation is a major cause of deterioration that may be detected by the formation of volatile degradation products.\(^{(34,81,82)}\)

Applications of sensor arrays to food have been reviewed.\(^{(83)}\)

4.2 Environment

4.2.1 Chemicals in Air

HS is obviously the technique of choice for air pollution. This topic starts with indoor pollutants imparting, for example, an off-odor in a smoker’s office.\(^{(30)}\) The composition of outside air reflects the great variety of human activity. It can be controlled at this level, or emitting sources like incinerators may be monitored online.\(^{(76)}\) Diurnal variations in the production of natural organics (e.g. isoprene) released by green plants in the atmosphere can be followed.\(^{(70)}\) An uncommon hyphenation with microwave-induced plasma detection HSGC/(MIP) has been used to investigate the effect of methylmercury on wildlife.\(^{(84)}\)

4.2.2 Water Pollutants

This has been the area of predilection for the development of P&THS.\(^{(11,20)}\) Membrane techniques\(^{(53)}\) have appeared, but HSSPME has gained a great popularity because of its simplicity.\(^{(63)}\)

4.2.3 Soil Contamination

In addition to the usual methods (extraction, column partitioning), SHS and P&THS are useful. However, preparing representative calibration standards is difficult because of the heterogeneous nature of the matrix. This problem can be overcome by MHE which does not require any spiking of the matrix for the calibration.\(^{(7,8)}\)

4.2.4 Pollutants in Food

Undesirable volatile compounds contaminating foods and beverages may be monitored by HS techniques. They can originate from agricultural treatments, from the animal feeding chain, or from monomers coming from the packaging polymer, and so on.\(^{(6,29,85)}\)

4.3 Health and Biosciences

This section includes pharmaceutical and medical applications, forensic science, and fermentative processes.
4.3.1 Metabolites from Fermentative Processes

Although HS analyses are unable to provide direct information about bacteria, these latter may be recognized from their metabolites.\(^\text{86}\) Using precursors labeled with stable isotopes, biological pathways leading to the production of volatiles in yogurt have been investigated.\(^\text{87,88}\) The production of human growth hormone by \textit{Escherichia coli} was monitored with a sensor array.\(^\text{89}\)

HSSPME allows a quick analysis of aroma compounds generated by staphylococci.\(^\text{48}\)

4.3.2 Health Diagnostic and Forensic Science

HS is very useful for the detection of volatiles in biological fluids, such as alcohol in blood,\(^\text{89,90}\) odorants in urine,\(^\text{22}\) and toxic substances in cadavers.\(^\text{91,92}\) HS methods, mainly static ones, applied to biological samples to analyze carbon monoxide, alcohols and their metabolites, solvents, gases, hydrogen cyanide and endogenous volatile metabolites have been reviewed.\(^\text{102}\)

Direct HSMS hyphenation has permitted the real-time monitoring of volatiles in breath. As an example, smokers were shown to breath out benzene and acetonitrile as long as 1 week after stopping smoking (Figure 10).\(^\text{70,93}\)

4.3.3 Pharmacy

HSGC analysis is used to analyze pharmaceutical products.\(^\text{94}\) Main applications relate to the determination of residual solvents or other volatile impurities,\(^\text{86}\) the evaluation of residual ethylene oxide used as a sterilizing agent\(^\text{86}\) and active ingredients such as medicinal plants and flowers.\(^\text{73}\)

4.4 Other Applications

References dealing with method development and phase equilibria are not mentioned in this section as details are given in sections 2, 3 and 6.

4.4.1 Agriculture

Pests are sometimes attracted by volatiles emitted by colonized plants. HS analyses enable scientists to determine possible attractants.\(^\text{95}\) In the same way fly pheromones were identified.\(^\text{86}\)

4.4.2 Polymers

Polymers often contain residual solvents, monomers and antioxidants that are analyzed after desorption and HS.\(^\text{38}\) Gas permeation through polymers used as packaging material can be investigated by HS.\(^\text{80}\)

5 COMPARISON OF RECOVERY EFFICIENCIES OF HEADSPACE METHODS

Equations given in the “theoretical recovery” sections of this article (sections 2.1.2, 2.2.2, 2.3.2, 2.4.2), allow expected results from various techniques to be compared (Table 1). SHS is not included, as its yield is a fraction of that of S&THS. Partition coefficients and recoveries vary in the same direction, for SHS, S&THS and P&THS. HSSPME does not exhibit the same trend, owing to the previously mentioned fact (section 2.4.2) that recoveries were close to those of a direct contact of the fiber with the liquid. HSSPME for 1 and 100 mL HS and the same sample amount (1 mL) illustrate the lower yields with increasing gas volumes. Highest theoretical recoveries are obviously observed for P&THS, which is itself less efficient than SDE,\(^\text{72}\) a non-HS technique which is, however, based on volatilities of solutes.

Some experimental method comparisons have been published. HSSPME gave lower detection limits (DLs) than SHS, and both results were highly correlated when applied to the quantitation of alcohols and esters in beer.\(^\text{47}\) Similar DLs were observed for substituted benzenes in water using HSSPME and P&THS and quantitative results with both techniques were also strongly correlated.\(^\text{63}\)

More generally, DLs were in the parts per million range for SHS, in the parts per billion range for SPME, solid-phase extraction, liquid extraction, and in the parts per billion range for P&THS.\(^\text{97}\) Experimental recovery comparisons with other, HS and non-HS, sample preparation techniques (extraction, SDE) have been

S&T/THS $V_1 = 2$ mL, $V_g = 300$ mL. P&T/THS $V_1 = 5$ mL; $F \times t = 200$ mL. ($F \times t$ is the total volume of stripping gas).

SPME $V_1 = 1$ mL; $V_g = 1$ or 100 mL; $V_1 = 1.32 \times 10^{-4}$ mL for a film thickness of 7 µm.

Additional numerical values for HSSPME and P&T/THS have been given elsewhere.\(^{72}\)

6 DETERMINATION OF THERMODYNAMIC CONSTANTS

HSGC is not only a unique tool in chemical analysis, it can also be used to measure thermodynamic parameters characterizing equilibria between phases, interactions between compounds, and so on. Only three examples are given here: air-to-liquid and liquid-to-liquid partition coefficients and activity coefficients.

6.1 Air-to-liquid Partition Coefficients

The gas-to-liquid partition coefficient may be determined by several methods. For instance, using SHS and the “vapor phase calibration” method,\(^{11}\) an aliquot of the HS is injected after fully vaporizing a known amount of volatile in a closed empty vial of volume $V_v$. The same amount is introduced into another closed vial, of the same volume, containing a volume $V_s$ of solvent. Two peak areas $A_s$ and $A_g$, respectively, are obtained. The coefficient is then calculated as, Equation (10):

$$k_{gl} = \frac{A_g V_s}{A_c V_v - A_g V_g}$$  \hspace{1cm} (10)

As many methods involve conditions that may alter sampled quantities (full vaporization calibration, pressure change in the vial during sampling, adsorptions and leaks when using glass syringes, and so on), a more sophisticated method has been proposed using the S&T/THS cell shown in Figure 5.\(^{39}\) GC peak areas versus initial concentrations in the liquid phase form a straight line of slope $p$. Determining this slope using two different volumes of the liquid sample, $V_{11}$ and $V_{12}$ gives two values $p_{11}$ and $p_{12}$. Using the ratio $\rho = p_{11}/p_{12}$, the air-to-liquid partition coefficient is given by Equation (11):

$$k_{gl} = \frac{(1 - \rho)V_{11} V_{12}}{(\rho V_{12} - V_{11}) V_g}$$  \hspace{1cm} (11)

6.2 Liquid-to-liquid Partition Coefficients

For a volatile solute, these can be indirectly determined from separate measurements of the two air-to-liquid partition coefficients of the volatile in each solvent, Equations (12) and (13):

$$k_{gl}^{\prime} = \frac{C_g^\prime}{C_l^\prime}$$  \hspace{1cm} (12)

$$k_{gl}^{\prime\prime} = \frac{C_g^{\prime\prime}}{C_l^{\prime\prime}}$$  \hspace{1cm} (13)

where $k_{gl}^{\prime}$ and $k_{gl}^{\prime\prime}$ are the air-to-liquid partition coefficients in both systems.

As both gas phase concentrations are equal at equilibrium, Equation (14):

$$k_{ll} = \frac{C_l}{C_l} = \frac{k_{gl}^{\prime}}{k_{gl}^{\prime\prime}}$$  \hspace{1cm} (14)

where $k_{ll}$ is the liquid-to-liquid partition coefficient.

This has been applied to calculate water-to-fat partition coefficients because extracting organic solutes from a fat to determine their concentration is not easy.\(^{99}\)

6.3 Activity Coefficients\(^{100}\)

For ideal solutions (no interaction between components of the mixture), the partial pressure $p_i$ of a given published.\(^{98}\) Direct thermal desorption of volatiles from a solid mentioned in section 2.2.1 was found to be more reproducible and to yield less artifacts than SDE under atmospheric pressure.\(^{14}\)
compound in the vapor phase obeys Raoult’s law, Equation (15):

\[ p_i = p_0^i x_i \]  

(15)

where \( p_i \) is the vapor pressure of compound \( i \) and \( x_i \) is the molar fraction of \( i \) in the mixture.

However real solutions often deviate from this ideality, then Henry’s law applies, Equation (16):

\[ p_i = p_0^i \gamma_i x_i \]  

(16)

where \( \gamma_i \) is the activity coefficient of \( i \).

As the GC peak area of a volatile is proportional to its partial pressure in the gas phase, Henry’s law for a binary mixture can be rewritten as, Equation (17):

\[ \frac{A_i}{\lambda} = \frac{A_0}{\lambda^0} \gamma_i x_i \]  

(17)

where \( \lambda, \lambda^0 \) are GC response factors.

Considering GC response factors to be independent of the concentration, \( \lambda = \lambda^0 \), then, measuring GC peak areas from the HS of pure \( i \) and in the mixture gives the activity coefficient, Equation (18),

\[ \gamma_i = \frac{A_i}{A_0} \frac{x_i}{\lambda^0} \]  

(18)

By stripping a solution with an inert gas and HSGC analysis using thermal conductivity and a FID in series, the determination of activity coefficients of volatile solutes and water activity were realized in a single operation.\(^{(101)}\)

### 6.4 Other Thermodynamic Constants

Other properties of volatile substances may be characterized by HSGC. The reader is invited to consult references cited for vapor pressures, partial free molar energy of mixing,\(^{(1)}\) fugacity\(^{(102)}\) and interactions with nonvolatile solutes (e.g. proteins): number of binding sites, intrinsic affinity constant, enthalpy, entropy and free energy of binding.\(^{(103,104)}\)

### 7 CONCLUSION

Innovation in the HS area since the late 1980s has been characterized by three main topics:

- Automation of injectors allowing a better reproducibility. Consequently the quantitative performances have been improved as well.
- Invention of SPME, and its application to HS. Its simplicity has been responsible for its rapid popularity.
- Direct hyphenation of HS and detectors. The greatest development was dedicated to sensor arrays, but additional efforts are required to improve their sensitivity and to mimic the human nose better. New alternatives like HSMS are only in their infancy, but seem very promising because they give a more informative response.

Starch is quantitatively an important component of the human diet, being present in grains, tubers and legumes. Starch has for a long time been considered by many as being slowly but completely digested in the small intestine, resulting in modest glycemic responses and with no physiological role other than as an energy source. It is now understood that in fact the metabolic fate and physiological properties of starch can vary considerably, and both the botanical source and the effects of food processing are major determinants of starch digestibility. In addition to the nature of the starch itself, the site, rate and extent of digestion of starch in the human small intestine are influenced by a number of host factors. The rate at which starch is digested in the human small intestine results in a wide range of glycemic responses, and this physiological measurement has been used to rank foods by their glycemic index. In vitro studies have indicated that glycemic response and the rate of starch digestion are closely correlated. Rapidly digestible starch (RDS) and slowly digestible starch (SDS) fractions together represent the starch that is likely to be digested completely in the human small intestine, with any remaining starch defined as the resistant starch (RS) fraction that is available for fermentation in the large bowel. Measurements of RDS, SDS and RS can be obtained by one simple procedure. Values for the different starch fractions obtained by the in vitro method described here represent reproducible measurements that can be used to classify dietary starch according to its potential digestibility. In addition to these starch fractions, two terms, rapidly available glucose (RAG) and slowly available glucose (SAG), are introduced to reflect the rate at which glucose (from both sugars and starch) is likely to be absorbed in the small intestine.

The proportions of RAG, SAG, RDS, SDS and RS in foods can be controlled by food processing. The implications of altering the rate and extent of starch digestion are potentially of great importance to public health. A full understanding of the links between dietary carbohydrates and health and the underlying mechanisms will come only from the specific measurement of individual types of dietary carbohydrates.

1 INTRODUCTION

Advances in knowledge of the relations between diet and disease have implicated the importance of dietary carbohydrates. A full understanding of the links between dietary carbohydrates and health and the underlying mechanisms will come only from the specific measurement of individual types of dietary carbohydrates. Table 1 shows the overall nutritional classification of plant carbohydrates in the human diet. This classification is based primarily on carbohydrate chemistry, with groupings and sub-divisions related to nutritional and physiological properties.

Starch is composed of D-glucose units and exists as a mixture of two polymers, amylose and amylopectin. Amylose is an essentially linear compound with an average degree of polymerization (DP) of 500 with mainly α-D-(1-4)-glucosidic bonds. It has a helical structure...

NSP, nonstarch polysaccharides; FSG, free-sugar glucose.

with a hydrophobic cavity allowing complexation with hydrophobic molecules such as lipids and iodine (giving the characteristic blue–black color). Amylopectin has a DP in the thousands with α-D-(1–4)-linked chains extensively branched through α-D-(1–6)-glucosidic linkages (about 5% of the total linkages). The ratio of amylose to amylopectin varies considerably between species and has been manipulated by selective breeding to produce both high-amylose and high-amylopectin (waxy) varieties of several cereals.

Starch is the storage polysaccharide of many higher plants, especially cereals, legumes and most tubers. In the plant, starch is stored within the cells as partially crystalline granules. An extensive review of the physical characteristics of starch granules has been given by Gallant et al.\(^1\) The size and shape of the granules and the crystal structure within them are characteristic of the botanical source. Starch granules have been characterized as type A, B or C according to their X-ray diffraction pattern.\(^2,3\) In general, cereal starches have the type A pattern, starches from tubers such as potatoes tend to have the type B pattern, and C-type starch, found in some legumes, is a combination of the A and B patterns. In general, starch granules with B or C type patterns are more resistant to digestion by pancreatic amylase, although the degree of resistance varies with botanical origin.\(^4\) This resistance to hydrolysis affects the digestibility of starchy foods that are normally eaten raw, such as bananas, and of processed foods such as biscuits in which the starch is incompletely gelatinized.

Heating starch granules in a moist environment leads to loss of the crystalline structure, swelling and leaching of amylose molecules from the granules. This process, known as gelatinization, usually occurs in the temperature range 50–70 °C, or at higher temperatures in low-moisture conditions. Cooling of gelatinized starch results in gelation and retrogradation, which is the recrystallization of the starch molecules, particularly amylose, into a form with the type B X-ray pattern.

Starch enclosed within particulate matter or plant cell walls and starch in the form of intact granules is digested slowly, because the physical access of amylolytic enzymes is restricted. Disruption of the particulate matter and removal of plant cell walls during food processing, especially milling, increase the surface area and can damage the structure of starch granules, increasing the susceptibility to enzymatic degradation. Gelatinization tends to increase and retrogradation to reduce starch digestibility. Colonna et al. have provided a detailed account of the influence of food processing on starch granules and their digestion.\(^5\)

The rate at which starch is digested in the human small intestine results in a wide range of glycemic responses, and this physiological measurement has been used to rank foods by their glycemic index.\(^6\) In vitro studies have indicated that glycemic response and the rate of starch digestion are closely correlated.\(^7–15\)

Starch that escapes digestion in the small intestine is termed RS, which, by definition, reaches the large intestine and is a potential substrate for microbial fermentation.\(^16\) The main end-products of this
fermentation are the gases hydrogen and carbon dioxide, and methane in about 50% of people, and short-chain fatty acids, which may be absorbed and utilized.\(^{17}\)

It is clear from this brief discussion that the metabolic fate and physiological properties of starch can vary considerably, and that the botanical source and the effects of food processing are major determinants of starch digestibility. In addition to the nature of the starch itself, the site, rate and extent of digestion of starch in the human small intestine are influenced by a number of other factors. These include the extent of chewing, the rate of gastric emptying, the transit time of food along the small intestine, the concentration of pancreatic amylase available for breakdown of the starch, the amount of starch consumed and the influence of other food components that may inhibit enzymatic hydrolysis.\(^{18}\)

The rate and extent of digestion of starch in vivo is variable both within and between individuals, which is recognized in the definition of RS as “the starch (and starch degradation products) that, on average, reaches the human large intestine”.\(^{16}\) The values for the different starch fractions obtained by the method described here represent reproducible in vitro measurements that can be used to classify dietary starch according to its potential digestibility.

Measurements of RDS, SDS and RS can be obtained by one simple procedure.\(^{16,18,19}\) RDS and SDS fractions together represent the starch that is likely to be digested completely in the human small intestine, with any remaining starch defined as the RS fraction. Three types of RS have been categorized: physically inaccessible starch (RS1), resistant starch granules (RS2) and retrograded starch (RS3).

In addition to these starch fractions, two terms, RAG and SAG, reflect the rate at which glucose is likely to be absorbed in the small intestine. RAG and SAG may include glucose derived from RDS and SDS, respectively, but the glucose may be derived from sugars. FSG is usually included in the RAG fraction, but may form part of the SAG fraction if trapped within particulate matter or plant cell walls. This ambiguity as to what proportions of the SAG fraction if trapped within particulate matter usually included in the RAG fraction, but may form part of the RAG fraction if trapped within particulate matter or plant cell walls.

Table 2 shows the proportions of the various fractions of starch and the RAG values for a range of foods. These fractions are all expressed in units of grams per 100 g of food “as eaten”. The legumes have the lowest RAG values, which are associated with low levels of free sugar and a low proportion of starch measuring as RDS. The cause of the slow and incomplete digestion of legume starch is probably a combination of starch granules being encapsulated by cell walls (dietary fiber) and not being fully gelatinized. Spaghetti, macaroni and pearled barley are examples of foods that have a moderate RAG value.

The proportions of RAG, SAG, RDS, SDS and RS in foods, and thus the expected rate and extent of digestion in the human small intestine, can be controlled by food processing. The implications of altering the rate and extent of starch digestion are potentially of great importance to public health. The identification of specific health benefits related to the ingestion of various types of starch will be possible only when separate measurements of these are available. It is therefore important to be able to measure nutritionally relevant starch fractions in vitro, and such methods are the subject of this article.

2 HISTORY

The classification and measurement of dietary carbohydrates have developed during the 20th century as knowledge of the nutritional importance of this fraction of the diet has accumulated. The perception of dietary carbohydrates as simply an energy source has been echoed in the traditional calculation of “carbohydrate by difference”, as the portion remaining once moisture, protein, fat and ash are accounted for.

In 1929, McCance and Lawrence highlighted the general lack of available data for the carbohydrate content of foods and the enormous variation that existed between some of the published values. They were well aware that the carbohydrate composition of raw and cooked foods can be very different and they identified the limitation of much of the available data, which were nearly all for the composition of raw foods. McCance and Lawrence were primarily concerned with the dietary management of diabetes, and they made the distinction between “available” and “unavailable carbohydrates”. They identified available carbohydrates as starch and the soluble sugars, sucrose, glucose and fructose.

McCance and Lawrence compiled a table of the available carbohydrate content of a range of plant foods, which were analyzed in the form in which they were normally eaten, i.e. cooked or raw as appropriate. They used hydrolysis with hot 7.5% (v/v) hydrochloric acid under a reflux condenser, followed by neutralization with sodium hydroxide, and they measured both reducing sugars and pentoses.

McCance and Lawrence introduced two important principles into the measurement of dietary carbohydrates for nutritional purposes: (1) the need to analyze foods in the form in which they were eaten; and (2) the need to make specific chemical measurements of dietary carbohydrates. The analysis and measurement of dietary carbohydrates in later years has been greatly facilitated by the advent of highly purified enzyme preparations and advances in techniques for the separation and specific measurements of individual sugars.

Increased interest in dietary fiber (plant cell walls) as a potentially protective agent against Western diseases of affluence led to the development of the NSP-type measurement techniques for the dietary carbohydrates that McCance and Lawrence referred to as unavailable. This type of procedure was pioneered by Southgate and later developed by Englyst, who identified a fraction of RS3 that could not be hydrolyzed without prior dispersion with dimethyl sulfoxide (DMSO) or KOH. This starch fraction, subsequently identified as RS3, was termed RS. Later, in conjunction with ileostomy studies, two other forms of RS were identified: RS1 and RS2. The definition of RS includes all three fractions, and no starch is included in the measurement of NSP.

There is growing interest in the rate and extent of starch digestion with respect to the magnitude of the glycemic response. Jenkins et al. have pioneered the glycemic index, which may be used to rank foods by their likely effect on the glycemic response. In a classical study, Haber et al. demonstrated the effect of particle size, i.e. degree of food processing, on the rate of absorption of sugars from apples, and several in vitro studies have shown that the rate of starch digestion varies according to its botanical source and degree of processing. Measurement of RAG, SAG and starch fractions as described here represent tools for studying the mechanisms that underlie the links between dietary carbohydrates and health.

3 APPLICATIONS OF STARCH

3.1 Food Tables and Food Labeling

Food tables should supply meaningful, reliable data that are suitable for use by dietitians, epidemiologists and the food industry. The Food and Agriculture Organization (FAO) of the United Nations and the World Health Organization (WHO) have recommended that compositional data for dietary carbohydrates for use in food tables and food labeling should be based on chemically identified components, which may be further subdivided by nutritional properties. The classification of dietary carbohydrates presented in Table 1 conforms with these criteria. The inclusion in food tables of the RDS, SDS and RS subdivisions of starch provides the tools for investigating the health implications of altering the rate and extent of starch digestion. The RAG and SAG terms provide information on the rate at which glucose from starch and sugars is likely to become available for absorption in the human small intestine.
and may be used as a guide to the likely magnitude of
the glycemic response.\(^{(19)}\) Such values do not become
obsolete and can be used in different combinations for
different purposes. The use of these values for food
labeling will depend on confirmation of their importance
for public health.

### 3.2 Public Health

A review of current knowledge suggests that a diet
rich in slowly digested carbohydrates has an overall
protective effect against the non-communicable diseases
of westernization.\(^{(28,29)}\) The results of epidemiological
studies have suggested that diets with a high content
of rapidly digested carbohydrates from refined foods
increase the relative risk of developing diabetes mellitus
and coronary heart disease.\(^{(29–32)}\) There are indications
from studies with low glycemic index diets that the rate of
starch digestion is of importance in the glycemic control
of people with diabetes.\(^{(33)}\)

The impact of RS on health remains uncertain. It
has been suggested that the high proportion of butyrate
produced during the fermentation of RS in the colon
may benefit the gut epithelium and act as a protective
agent against colon cancer. However, caution should be
applied until the health implications of RS fractions have
been assessed, and safe levels of RS intakes have been
determined.

### 4 METHODS

The main analytical procedure described here quanti-
tifies the various fractions of starch through enzymatic
hydrolysis and measurement of the glucose released.
Samples are analyzed “as eaten” and are treated with
protease to disrupt any starch–protein interaction. This
is followed by incubation with amylolytic enzymes under
conditions controlled for temperature, pH, viscosity and
rate of mechanical mixing. Subsamples are taken at 20 min
[the glucose measured in the portion removed from the
analysis at 20 min after the addition of enzymes (G20)]
and 120 min [the glucose measured in the portion removed
from the analysis at 120 min after the addition of enzymes
(G120)] as measures of the rate and extent of starch
digestion. Any remaining starch is dispersed before enzy-
matic hydrolysis to give a value for total glucose (TG). A
value for RS is calculated as the difference between G120
and TG. Separate values may be obtained for RS1, RS2
and RS3.

Two versions of the main procedure are described: one
is based on the colorimetric determination of glu-
cose and the other on the measurement of glucose by
high-performance liquid chromatography (HPLC), which
includes the use of an internal standard. Figures 1 and 2
summarize the colorimetry and HPLC procedures.

The subsidiary procedure for the measurement of FSG
is described, which is required for calculation of RDS and
TS, and this procedure may be used to obtain a rapid
measurement of TS.

Regarding analytical throughput, a shaking water-bath
capable of holding 18 tubes allows the analysis of five test
samples in triplicate. Both the main and the subsidiary
procedures may be completed within a working day.

### 4.1 Reagents

#### 4.1.1 Common to the Colorimetry and High-performance
Liquid Chromatography Procedures

Distilled water or water of equivalent purity should be
used throughout the method. All sugars should be dried to
constant weight under reduced pressure with phosphorus
pentoxide before use.

- **Amyloglucosidase** EC 3.2.1.3 (Englyst Carbohydrate
  Services Ltd, Cat. No. 61-002).
- **Amyloglucosidase Solution** Amyloglucosidase dilu-
ted 1:7 (v/v) with water.
- **Benzoic Acid, Saturated** Prepare a saturated solution
  of benzoic acid at room temperature.
- **Enzyme Mixture** For 18 samples/standards, into each
  of six centrifuge tubes weigh 3.0 g of pancreatin and
  suspend in 20 mL of water using a vortex-mixer. Add
  a magnetic stirring bar and mix for 10 min. Centrifuge
  at 1500 \(g\) for 10 min, then remove 15 mL of the cloudy
  supernatant from each tube and combine (90 mL total).
  Add 4 mL of amyloglucosidase and 6 mL of invertase.
  Mix well. The enzyme mixture should be prepared
  immediately before use.
- **Guar Gum Powder** (Sigma, Cat No. G-4129).
- **Heat-stable Amylase** EC 3.2.1.1 (Termamyl, Englyst
  Carbohydrate Services Ltd, Cat. No. 61-005).
- **Hydrochloric Acid** 0.05 \(mol \text{L}^{-1}\).
- **Invertase** EC 3.2.1.26 (Merck, Cat. No. 39020).
- **Pancreatin** (Sigma, 8 × USP, Cat. No. P-7545).
- **Pepsin Powder** EC 3.4.23.1 (Sigma, Cat. No. P-7000).
- **Pepsin–Guar Gum Solution** For 18 samples/stand-
  ards, add 1 g of pepsin powder to 200 mL of 0.05 \(mol \text{L}^{-1}\)
  hydrochloric acid and mix with a magnetic stirring
Sample (0.6 – 4 g) 
Add 10 mL pepsin–guar gum 
30 min at 37°C 
Add 10 mL 0.25 mol L⁻¹ sodium acetate 
Add 5 glass balls 
Add 5 mL enzyme mixture (pancreatin, amyloglucosidase, invertase) 
Incubate with shaking at 37°C 
After 20 min remove 0.5 mL 
After 120 min remove 0.5 mL 
Vortex-mix remainder 
30 min at 100°C 
Cool to 0°C. Add 10 mL 7-mol L⁻¹ KOH 
Vortex-mix 
30 min at 0°C with shaking 
Vortex-mix. Transfer 1 mL into 10 mL 0.5-mol L⁻¹ acetic acid 
Add 0.2 mL amyloglucosidase 
30 min at 70°C 
Add 40 mL water 
Centrifuge 
Measure total glucose (TG) 

Add 20 mL buffer 
Add 5 glass balls 
Vortex-mix vigorously 
30 min at 100°C 
Add 0.2 mL invertase 
Incubate with shaking 
30 min at 37°C 
Transfer 0.5 mL into 10 mL ethanol 
Centrifuge 
10 min at 100°C 
Measure glucose released after 20 min (G20) 
Measure glucose released after 120 min (G120) 

Place in 20 mL ethanol 
Add 0.2 mL invertase 
30 min at 0°C with shaking 
Centrifuge 
Incubate with shaking 
30 min at 37°C 
Transfer 0.5 mL into 10 mL ethanol 
Centrifuge 
30 min at 100°C 
Measure free sugar glucose (FSG) 

Figure 1 Flow diagram of the steps in the colorimetry version of the procedure.

bar. Just before use, add 1 g of guar gum and mix well. The pepsin–guar gum solution should be prepared immediately before use.

Potassium Hydroxide 7 mol L⁻¹.

Sodium Acetate Buffer 0.1 mol L⁻¹, pH 5.2 Dissolve 13.6 g of sodium acetate trihydrate in water, add 250 mL of saturated benzoic acid solution and make up to 1 L with water. Adjust to pH 5.2 with 0.1 mol L⁻¹ acetic acid. To stabilize and activate enzymes, add 4 mL of 1 mol L⁻¹ calcium chloride to 1 L of buffer.

4.1.2 For Colorimetry Only

Acetic Acid 0.5 mol L⁻¹. Plus 4 mL L⁻¹ of 1 mol L⁻¹ calcium chloride.

Ethanol 66% (v/v).

Glucose Oxidase Diagnostic Kit [Boehringer glucose test combination, Cat. No. 166391].

Glucose Standard Weigh 50 g of glucose to the nearest 0.1 mg. Make up to 200 mL with sodium acetate buffer to give a 25 mg mL⁻¹ solution.

Sodium Acetate 0.25 mol L⁻¹. Weigh 34 g of sodium acetate trihydrate and make up to 1 L with water.

4.1.3 For the High-performance Liquid Chromatography Procedure Only

Acetic Acid 1 mol L⁻¹. Plus 4 mL L⁻¹ of 1 mol L⁻¹ calcium chloride.

Ethanol Absolute.
Sample (0.6–4 g)
Add 5 mL internal standard (arabinose)
Add 10 mL pepsin–guar gum
30 min at 37°C
Add 5 mL 0.5 mol L⁻¹ sodium acetate
Add 5 glass balls
Add 5 mL enzyme mixture (pancreatin, amyloglucosidase, invertase)
Incubate with shaking at 37°C
After 20 min remove 0.2 mL
After 120 min remove 0.2 mL
Vortex-mix remainder
30 min at 100°C
Cool to 0°C. Add 10 mL 7 mol L⁻¹ KOH
Vortex-mix
30 min at 0°C with shaking
Vortex-mix.
Transfer 0.2 mL into 1 mL 1 mol L⁻¹ acetic acid
Add 40 µL amylglucosidase
30 min at 70°C
10 min at 100°C
Add 12 mL ethanol
Centrifuge
Transfer 200 µL into vial
Add 1 mL water
Vortex-mix
Measure total glucose (TG)
Add 5 mL internal standard
Add 20 mL water
Add 5 glass balls
Vortex-mix vigorously
30 min at 100°C
Add 0.2 mL invertase
Incubate with shaking 30 min at 37°C
Transfer 0.5 mL into 10 mL ethanol
Centrifuge
Transfer 70 µL into vial
Add 1 mL water
Vortex-mix
Measure glucose released after 20 min (G20)
Measure glucose released after 120 min (G20)

Figure 2 Flow diagram of the steps in the HPLC version of the procedure.

**Internal Standard**  Dissolve 40 g of arabinose in water, add 500 mL of saturated benzoic acid and make up to 1 L with water.

**Stock Sugar Mixture**  Dissolve 50 g of glucose and 25 g of fructose in water, add 500 mL of saturated benzoic acid and make up to 1 L with water.

**Sodium Acetate**  0.5 mol L⁻¹. Weigh 68 g of sodium acetate trihydrate and make up to 1 L with water.

**Sodium Hydroxide**  50% (w/v).

### 4.2 Apparatus

#### 4.2.1 Common to the Colorimetry and High-performance Liquid Chromatography Procedures

**Balance**  Accurate to 0.1 mg.

**Centrifuge**  Capable of exerting 1500 g.

**Centrifuge Tubes**  Polypropylene (Copolymer) centrifuge tubes of length 11.5 cm and diameter 3 cm (50-mL capacity), with screw caps (Alpha Laboratories, Cat. No. LW 1110).
**Glass Balls (Marbles)** Approximately 1.5 cm in diameter, sufficient to provide five balls per sample.

**Magnetic Stirrer**

**Mincer** Hand-driven, with a plate with 0.9-cm diameter holes.

**Test Tubes** Glass or plastic, of 15- and 30-mL capacity, preferably with lids, capable of withstanding low-speed centrifugation.

**Vortex-mixer**

**Water-bath** Capable of maintaining 100°C.

**Water-baths** Capable of maintaining temperatures in the range 35–70°C. This or another similar bath must have a linear shaking capacity of not less than 160 strokes min⁻¹ and a stroke length of approximately 35 mm. The shaking bath must be fitted with the means to hold all the centrifuge tubes exactly horizontally under the water, with the long axis of each tube exactly parallel with the direction of movement. Each bath should be of sufficient capacity that there is no significant change in temperature when a rack containing all the tubes is placed in it.

4.2.2 For the Colorimetry Procedure Only

**Spectrophotometer**

4.2.3 For the High-performance Liquid Chromatography Procedure Only

**Autoinjector**

**Ion-exchange Column with Guard Column** For separation of sugars.

**Ion-exchange Column** For trapping amino acids and peptides.

**Column-switching Mechanism**

**Gradient Pump**

**Electrochemical Detector**

**Computerized Data-handling System**

4.3 Sample Preparation

Starch digestibility is greatly influenced by food processing and samples must be analyzed as eaten. Foods normally eaten dry are analyzed dry, and foods normally eaten hot and wet are cooked and maintained at 70–80°C immediately before analysis. Foods with a recognizable structure that would normally require chewing (e.g. pasta, rice, maize) are passed through the mincer. For determination of FSG and the rapid measurement of TS, samples may be milled or homogenized. Determine the moisture content of samples as weight loss after overnight incubation at 104°C.

Sample weights should be chosen to contain 500–600 mg of starch and sugars, which can be estimated from food tables. Examples of suitable sample weights are given in Table 3.

The procedure should now continue, using either the colorimetry or the HPLC version.

4.4 The Colorimetry Version (Figure 1)

4.4.1 Measurement of Rapidly Available Glucose, Slowly Digestible Starch, Resistant Starch and Total Starch

**Preparation of the Standard and Blank** Into each of three centrifuge tubes weigh 50 mg of guar gum powder and add five glass balls. Pipet 20 mL of glucose standard into each of two of these and 20 mL of acetate buffer into the other (blank). Cap and shake well to disperse the gum. Treat these tubes exactly as the samples after the addition of sodium acetate.

**Sample Weight** Weigh an appropriate amount of sample, to the nearest 0.1 mg, into 50-mL tubes. If the sample is hot, cap the tube and place in a water-bath at 70–80°C until ready to analyze. Samples should be analyzed at least in duplicate. Reference samples should be included in every batch (see section 5).

**Incubation with Pepsin** Put 10 mL of the freshly prepared pepsin–guar gum solution into each sample tube, vortex-mix and place the tubes in a water-bath at 37°C. After 30 min of incubation, remove the samples from the water-bath and add five glass balls and 10 mL of 0.25 mol L⁻¹ sodium acetate to each tube. Shake the tubes gently to disperse the contents and replace the sample tubes, standards and blanks in the water-bath at 37°C to equilibrate.

**Enzymatic Hydrolysis of Starch** Remove one sample tube from the 37°C water-bath and add 5 mL of enzyme mixture. Immediately cap the tube and mix the contents gently by inversion before securing the tube horizontally in the 37°C shaking water-bath. Start the shaking action of the water-bath; this is time zero for the incubation

</table>
and the shaking action is not interrupted until all the G120 portions have been collected (see below). Repeat the addition of enzyme mixture for the rest of the sample tubes, at 1-min intervals to aid timing of the procedure, and place them into the shaking water-bath. Remove each tube from the bath at exactly 20 min after addition of the enzyme mixture, transfer 0.5 mL into 20 mL of 66% ethanol and vortex-mix to stop the hydrolysis; this is the G20 portion. Return the sample tube to the shaking water-bath immediately after the sample has been taken. After a further 100 min (a total of 120 min of incubation), transfer 0.5 mL from the sample tube into 20 mL of 66% ethanol and vortex-mix; this is the G120 portion.

Dispersion of Resistant Starch Having removed all the tubes from the shaking water-bath, vortex-mix vigorously to break up any large particles, then place the rack of tubes into a boiling water-bath for 30 min. Remove the tubes from the bath, vortex-mix and place the tubes in ice–water until thoroughly chilled. Add 10 mL of 7 mol L\(^{-1}\) KOH, cap the tube and mix the contents by inversion. Immerse the tubes horizontally in a shaking water-bath containing ice–water for 30 min.

Hydrolysis of Starch to Glucose Remove the samples from the waterbath and immediately transfer 1 mL of the contents into a 50-mL tube containing 10 mL of 0.5-mol L\(^{-1}\) acetic acid and mix well. Add 0.2 mL of amyloglucosidase solution to each sample. Mix and place in a water-bath at 70 °C. After 30 min, remove the rack of tubes to a boiling water-bath for 10 min. Cool the tubes to room temperature, add 40 mL of water, cap and mix; this is the TG portion to be measured in step 4.4.3.

4.4.2 Measurement of Free-sugar Glucose; Optional Rapid Measurement of Total Starch

Preparation of the Standard and Blank Into each of two 50-mL tubes, pipet 25 mL of glucose standard and into a third add 25 mL of sodium acetate buffer (blank). Treat these tubes exactly as the samples.

Pretreatment of the Samples Samples may be analyzed in the form in which they are eaten, as in the main procedure. Alternatively, samples may be finely divided by milling or homogenization before analysis, in which case the glass balls may be replaced by a magnetic stirring bar and mixing of the sample achieved with a magnetic stirrer instead of a shaking water-bath.

Measurement of Free-sugar Glucose Weigh an appropriate amount of sample, to the nearest 0.1 mg, into 50-mL tubes and add five glass balls to each. Pipet 25 mL of 0.1-mol L\(^{-1}\) sodium acetate buffer into each tube, cap and vortex-mix vigorously to begin breaking up large particles. Place the rack of tubes into a boiling water-bath. After 30 min remove the rack of tubes from the boiling water-bath and vortex-mix vigorously to break up any remaining particles of sample. Cool to 37 °C, then add 0.2 mL of invertase to each tube. Cap the tubes, immerse horizontally in the shaking water-bath at 37 °C and incubate for 30 min.

Vortex-mix vigorously before transferring 1 mL of each sample or standard solution into a test tube containing 2 mL of absolute ethanol and vortex-mix. Centrifuge at 500 g for 5 min, then transfer 1 mL of the supernatant into 5 mL of water and mix well by inversion. (For the standard, transfer 1 mL of supernatant into 20 mL of water.) This is the FSG portion to be measured in step 4.4.3.

If TS is to be determined by the main method, the procedure is finished; otherwise, the procedure can be continued for a rapid measurement of TS.

Measurement of Total Glucose To the remainder of the sample solution add 0.1 mL of heat-stable amylase, cap the tube, vortex-mix vigorously, then place in a boiling water-bath for 15 min. Remove the tubes from the bath, vortex-mix and then place the rack of tubes in ice–water and leave them to chill thoroughly.

Add 10 mL of 7 mol L\(^{-1}\) KOH, cap the tube and mix the contents by inversion. Immerse the tubes horizontally in a shaking water-bath containing ice–water for 30 min.

Remove the tubes from the water-bath and immediately transfer 1 mL into a 50-mL tube containing 10 mL of 0.5-mol L\(^{-1}\) acetic acid and mix well. Add 0.2 mL of amyloglucosidase solution to each sample. Mix and place in a water-bath at 70 °C. After 30 min remove the rack of tubes to a boiling water-bath for 10 min. Cool the tubes to room temperature, add 40 mL of water, cap and mix; this is the TG portion.

4.4.3 Determination of Glucose Using Glucose Oxidase

Centrifuge the samples at 500 g for 5 min to pellet any precipitate before determination of glucose.

Pipet 100 μL of water, enzyme blank, samples and standards in duplicate into test tubes containing 2 mL of the glucose oxidase reagent (prepared according to the manufacturer’s instructions) and vortex-mix. Place the tubes in a water-bath at 37 °C for 20 min. Measure the absorbance of the standards and samples in the spectrophotometer at 510 nm against the reagent blank. The glucose concentration (grams per 100 g of sample) is
the total volume of the test solution (milliliters), C

Remove the samples from the water-bath and add five glass balls to each. Add 5 mL of internal standard to the sample and blank tubes and treat as illustrated in Table 4.

4.5 The High-performance Liquid Chromatography Version (Figure 2)

4.5.1 Measurement of Rapidly Available Glucose, Slowly Digestible Starch, Resistant Starch and Total Starch

Sample Weight and Internal Standard and Blanks

Weigh an appropriate amount of sample, to the nearest 0.1 mg, into 50-mL tubes. If the sample is hot, cap the tube and place in a water-bath at 70–80 °C until ready to analyze. Samples should be analyzed at least in duplicate. Reference samples should be included in every batch (see section 5). Two tubes, one with 4 mL of stock sugar mixture added, are included as enzyme blanks. Add 5 mL of internal standard to the sample and blank tubes and treat exactly as the samples.

Incubation with Pepsin

Add 10 mL of the freshly prepared pepsin–guar gum solution to each tube, vortex-mix and place the tubes in a water-bath at 37 °C for 30 min. Remove the samples from the water-bath and add five glass balls and 5 mL of 0.5-mol L⁻¹ sodium acetate to each tube. Shake the tubes gently by inversion before securing the tube horizontally in the 37 °C shaking water-bath. Start the shaking action of the water-bath; this is time zero for the incubation and the shaking action is not interrupted until all the G120 portions have been collected (see below). Repeat the addition of enzyme mixture for the rest of the sample tubes, at 1-min intervals to aid timing of the procedure, and place them into the shaking water-bath. Remove each tube from the bath at exactly 20 min after addition of the enzyme mixture, transfer 0.2 mL into 4 mL of absolute ethanol and vortex-mix to stop the hydrolysis; this is the G20 portion to be measured in step 4.5.3. Return the sample tube to the shaking water-bath immediately after the sample has been taken. After a further 100 min (a total of 120 min of incubation), transfer 0.2 mL from the sample tube into 4 mL of absolute ethanol and vortex-mix; this is the G120 portion to be measured in step 4.5.3.

Dispersion of Resistant Starch

Having removed all the tubes from the shaking water-bath, vortex-mix vigorously to break up any large particles, then place the rack of tubes in a boiling water-bath for 30 min. Remove the tubes from the bath, vortex-mix and place the tubes in ice–water until thoroughly chilled. Add 10 mL of 7-mol L⁻¹ KOH, cap the tube and mix the contents by inversion. Immerse the tubes horizontally in a shaking water-bath containing ice–water for 30 min.

Hydrolysis of Starch to Glucose

Remove the tubes singly from the ice–water and transfer 0.2 mL of the contents into a tube containing 1 mL of 1-mol L⁻¹ acetic acid. To these tubes add 40 µL of amyloglucosidase solution. Mix and place the tubes in a 70 °C water-bath for 30 min followed by 10 min in a boiling water-bath. Cool the tubes to room temperature before adding 12 mL of absolute ethanol; this is the TG portion to be measured in step 4.5.3.

4.5.2 Measurement of Free-sugar Glucose; Optional Rapid Measurement of Total Starch

Preparation of Enzyme Blanks

No enzyme blank is required for the measurement of FSG. For the rapid measurement of TS, two tubes, one with 4 mL of the stock sugar mixture added, are included as enzyme blanks.

Pretreatment of the Samples

Samples may be analyzed in the form in which they are eaten, as in the main procedure. Alternatively, samples may be finely divided by milling or homogenization before analysis, in which case the glass balls may be replaced by a magnetic stirring bar and mixing of the sample achieved with a magnetic stirrer instead of a shaking water-bath.

Measurement of Free-sugar Glucose

Weigh an appropriate amount of sample, to the nearest 0.1 mg, into 50-mL tubes and add five glass balls to each. Add 5 mL of internal standard to each sample tube. Pipet 20 mL of 0.1-mol L⁻¹

ᵃ +1 mL per 1 g of sample.

given by Equation (1):

\[
\text{Glucose(%) = } \frac{A(t)V_C}{A(s)W} \tag{1}
\]

where \(A(t)\) is the absorbance of the test solution, \(V\) is the total volume of the test solution (milliliters), \(C\) is the concentration (milligrams per milliliter) of the standard used, \(A(s)\) is the absorbance of the standard used and \(W\) is the weight (milligrams) of sample taken for analysis (this figure may be corrected for moisture), as illustrated in Table 4.
acetate buffer into each tube, cap and vortex-mix vigorously in order to begin breaking up large particles. Place the rack of tubes in a boiling water-bath. After 30 min, remove the rack of tubes from the boiling water-bath and vortex-mix vigorously to break up any remaining particles of sample. Cool to 37 °C, then add 0.2 mL of invertase to each tube. Cap the tubes and immerse horizontally in the shaking water-bath at 37 °C for 30 min.

Vortex-mix vigorously before removing 0.2 mL of each sample or standard solution into a test tube containing 4 mL of absolute ethanol; this is the FSG portion to be measured in step 4.5.3.

If TS is to be determined by the main method, the procedure is finished here; otherwise, the procedure can be continued for a rapid measurement of TS.

**Dispersion and Hydrolysis of Total Starch**
To the remainder of the sample solution add 0.1 mL of heat-stable amylase, cap the tube, vortex-mix vigorously, then place in a boiling water-bath for 15 min. Remove the tubes from the bath, vortex-mix and place the tubes in ice—water until thoroughly chilled. Add 10 mL of 7-mol L⁻¹ KOH, cap the tube and mix the contents by inversion. Immers horizontally in a shaking water-bath containing ice—water for 30 min.

Remove the samples from the shaking water-bath and immediately transfer 0.2 mL of the contents into a tube containing 1 mL of 1-mol L⁻¹ acetic acid and mix well. Add 40 μL of amyloglucosidase solution. Mix and place the tubes in a 70 °C water-bath for 30 min followed by 10 min in a boiling water-bath. Cool the tubes to room temperature before adding 12 mL of absolute ethanol; this is the TG portion to be measured in step 4.5.3.

**4.5.3 High-performance Liquid Chromatography Analysis of Sugars**
Prepare two sugar standards in 50-mL tubes: standard 1, 1 mL of stock sugar mixture, 19 mL of water and 5 mL of internal standard; standard 2, 10 mL of stock sugar mixture, 10 mL of water and 5 mL of internal standard. Mix well and transfer 0.2 mL from each into a tube containing 4 mL of absolute ethanol.

Before HPLC analysis, centrifuge all the ethanolic fractions for 5 min at 500 g. The amount to be taken for analysis varies according to sugar content: typically 70 μL for the sugar standards and the G20 and G120 portions, 200 μL for the TG portions and 70–120 μL for the FSG portions. Place the samples in HPLC vials, add 1 mL of deionized water and vortex-mix.

A Dionex AS3500 autoinjector may be used for injection of 20 μL of the diluted ethanolic fractions. Sugar separation may be achieved with a Dionex Carbopac PA100 column using a Dionex GP40 gradient pump and a Dionex Carbopac PA10 guard column. Column switching and a Dionex Aminotrap may be used to prevent pancreatic peptides from reaching the analytical column. The eluents, high-purity water and 200 mol L⁻¹ NaOH [16 mL L⁻¹ of 50% (w/v) NaOH solution in high-purity degassed water] should be degassed. The flow-rate is 0.8 mL min⁻¹ and the elution conditions are shown in Table 5. Monosaccharide detection may be achieved with a Dionex ED40 electrochemical detector with the following pulse potentials, E, and durations, t: E₁: 0.05 V, t₁: 400 ms; E₂: 0.75 V, t₂: 200 ms; and E₃: 0.15 V, t₃: 400 ms. A response time of 1 s is used and the output on the detector is set at 300 nA.

#### 4.6 Calculations

Values for RAG, SAG, RDS, SDS, RS and TS are calculated from the measured FSG, G20, G120 and TG values according to Equations (2–7). Values for the starch fractions are expressed as polysaccharides, using a factor of 0.9 to convert the measured glucose value to polysaccharide.

\[
RAG = G20 \\
SAG = G120 - G20 \\
RDS = 0.9(G20 - FSG) \\
SDS = 0.9(G120 - G20) \\
TS = 0.9(TG - FSG) \\
RS = 0.9(TG - G120)
\]

#### 4.7 Measurement of Resistant Starch 1, 2 and 3 (Using Colorimetry or High-performance Liquid Chromatography)

##### 4.7.1 Resistant Starch 1, Physically Inaccessible Starch

There are three forms of RS: RS1 is present in foods having a dense or rigid structure, e.g. boiled rice, pasta,
whole-grain bread, maize and legumes; RS2 is present in raw foods, e.g. bananas, and raw cereal flours and grains, in foods cooked with very little water, e.g. some dry-baked biscuits, and in legumes; RS3 is present in foods that have been cooked and then cooled, e.g. bread, breakfast cereals and cold potatoes. (Note: for a few high-amylose products, e.g. Hylon VII, the boiling step in the procedure will not gelatinize all of the starch. Any starch that remains ungelatinized after this step will therefore be included as RS3.)

A value for total RS is obtained by the main procedure. Values for the individual RS1, RS2 and RS3 fractions may be obtained by the parallel analysis of three samples of the test food, which are prepared and analyzed in different ways.

Sample A is prepared in the form in which the food would normally be eaten, and is then passed through a hand-operated mincer. The analytical sample is weighed into 50-mL tubes and treated as described for the main procedure. Only the G120(A) value is required for calculation of the RS1 fraction but it is recommended that G20(A) and TG(A) are measured during the procedure and the values used for calculation of RAG, SAG and total RS.

Sample B is homogenized or milled as described for moist foods or milled for dry foods to disrupt the food matrix before analysis but ball milling should not be used, as this may damage starch granules. The analytical sample is weighed into 50-mL tubes and treated as described for the main procedure. Only the G120(B) value is required for calculation of the RS2 fraction.

Sample C is homogenized or milled as described for sample B. The analytical sample is weighed into 50-mL tubes and treated as described for the main procedure up to and including the addition of sodium acetate. At this stage, the tubes are placed in boiling water for 30 min to gelatinize any native starch granules that would normally be gelatinized during cooking. The tubes are cooled to 37°C and the remainder of the main procedure is followed to obtain the G120(C) value that is required for calculation of the RS2 and RS3 fractions. The analysis is continued to obtain a TG(C) value, which is required for calculation of the RS3 fraction. The step in the boiling water-bath in the main procedure after the G120(C) subsample has been withdrawn may be omitted, instead continuing with the dispersion of RS3 by treatment with KOH.

Calculations are performed using Equations (8–10).

\[
\begin{align*}
RS1 &= 0.9[G120(B) - G120(A)] \\
RS2 &= 0.9[G120(C) - G120(B)] \\
RS3 &= 0.9[TG(C) - G120(C)]
\end{align*}
\]

5 QUALITY CONTROL AND TROUBLESHOOTING

5.1 Quality Control

For reproducible results to be obtained within and between laboratories, it is essential that stringent quality control is applied. The procedures described here are based on the measurement of the rate and extent of starch digestion in vitro and require standardized enzyme preparations and incubation conditions. A kit is available (Englyst Carbohydrate Services Ltd, Cat. No. 61-000), which includes the necessary enzymes and three reference samples for calibration purposes. It is suggested that reference samples 1 and 2 are included in every batch of samples analyzed. The reference samples have been selected for their specific starch digestion profiles.

Reference sample 1 (white wheat flour; Homepride, UK), with its high SDS content, is used to check the efficiency of starch hydrolysis during the amylolytic incubation. Values for G120 that are too low (see target values below) may indicate that the activity of the amylolytic enzymes has decreased. Reference sample 2 (raw potato starch; Kartoffelmel Centrale, Denmark), with its high RS content, is used to establish the optimum stroke speed of the shaking water-bath during the amylolytic incubation. If the G120 value for the potato starch is too high (see target values in Table 6), decrease the stroke speed and vice versa, e.g. we observe a linear increase in the G120 value for reference sample 2 from 12.4 to 36.4 g per 100 g between 120 and 170 strokes min⁻¹.

Reference sample 3 (corn flakes; Kellogg’s, UK), with its high RDS content, is used to check the efficiency of starch and maltose hydrolysis during the first stage of amylolytic incubation. Values for G20 that are too low (see target values below) may indicate that the amyloglucosidase activity has decreased.

Target values for the three reference samples are given in Table 6.

The method yields coefficients of variation of 3.7% intraassay and 6.6% interassay for the measurement of RAG, 2.2% and 3.9% for G120 (RAG + SAG) and 1.6% and 2.5% for TG for the three reference samples.

5.2 Troubleshooting

5.2.1 Troubleshooting for the Common Hydrolysis Steps
Accurate timing during subsampling for G20 and G120 measurements is critical. Pitted glass balls may increase the mechanical disruption of the samples, and should be replaced. Failure to ensure that tubes are held exactly horizontal in the shaking water-bath and exactly parallel with the direction of movement may result in differences in mechanical disruption of samples.

Variation in Reference Sample Values Between Batches
Use the reference samples to check enzyme activity levels. Consistently low results may indicate incorrect pH during hydrolysis: check the buffer system. Variation in G120 values between batches for reference sample 2 may be due to changes in the shaking speed or the temperature of the water-bath. It is recommended that the shaking speed and temperature controls are physically fixed once optimized to the target values.

Variation in Replicate Analysis
The sample heterogeneity of many foods analyzed “as eaten” can make it difficult to take fully representative subsamples, leading to greater variation in results than for homogenized or milled samples. It is recommended that an increased number of replicates are analyzed for such problem samples.

5.2.2 Troubleshooting for the Colorimetric Procedure

Variation in Replicate Analysis
This may be due to inaccurate pipeting when taking subsamples for measurement of G20, G120 and TG, due to the presence of large food particles in the sample and/or the high viscosity of the suspension. The reproducibility of pipeting may be improved by cutting off the end of the pipet tip to produce a larger orifice and by the repeated washing of the pipet tip (after wiping the outside) into the ethanol fraction to ensure complete transfer of the subsample.

Variation in Absorbance Measurements
Accurate pipeting is essential, and may be improved by repeatedly washing the tip (after wiping the outside) into the color reagent to ensure complete transfer of the subsample. Ensure that each set of samples is analyzed with suitable standards and blanks, and that the interval between the addition of sample to the color reagent and the measurement of the absorbance is identical for all the samples, standards and blanks.

5.2.3 Troubleshooting for High-performance Liquid Chromatography Procedure

Variation Between Replicates
This may be caused by inaccurate pipeting during the addition of internal standard to the samples.

Spurious Peaks on the Chromatogram
Peaks that significantly interfere with the integration of sugar peaks may be due to amino acids or peptides in the sample that have eluted on to the separator column from the guard column intended for their retention. Clean the guard column or alter the timing of the column-switching mechanism.

6 METHOD DEVELOPMENT AND VALIDATION
The measurements of starch fractions obtained by the procedures described here characterize starchy foods in terms that reflect the average rate and extent of starch digestion in the human gut. Owing to the variation in both the rate and extent of starch digestion that is seen both within and between individuals in human studies, the measurement of RS is based on the average of measurements observed in vivo. The measurement of RAG, which includes RDS but is not limited to starch, has been shown to be correlated with in vivo glycemic response measurements.\(^{19}\)

6.1 Methodological Considerations
This section provides a brief discussion of the development of methodology for the measurement of nutritionally important starch fractions. A full description has been given in the papers cited below.

For foods with a well-defined particulate structure, the rate and extent of starch digestion are critically dependent on the way the food sample is divided and the method chosen should reflect the average disruption of food structure achieved by chewing. Comparison of the starch digestibility in food samples that were chewed before analysis and those minced as described here showed that, although both gave similar mean values, the values for the minced samples had a smaller standard deviation.\(^{18}\)

The addition of glass balls to the incubation tubes provides further mechanical disruption of particulate matter during the hydrolysis with pancreatic amylase. This allowed the determination of in vitro RS values for polished rice commensurate with the starch recovered in ileostomy studies with similar products. To prevent excessive grinding of starch granules by the glass balls, the viscosity of the sample mixture was increased by the addition of guar
FOOD

gum, which keeps the sample material in suspension. The amounts of the enzymes used in this procedure are calculated to be present in excess so that they are not rate-limiting in the hydrolysis of starch to glucose.

Three approaches are used to disperse the starch fraction that resists hydrolysis during the incubation with pancreatic α-amylase. Physical disruption of particulate material (RS1) by vigorous vortex-mixing at several stages is aided by the presence of the glass balls. A 30 min boiling step is used to gelatinize starch granules (RS2). Retrograded amyllose (RS3) is dispersed by 30 min treatment with 2 M KOH, at 0°C to avoid the destruction of sugars that can occur at higher temperatures. These treatments in combination have been shown to totally disperse starch in all but the hardest whole grains, which may require milling to obtain a reliable value for TS.

### 6.2 Validation of Rapidly Digestible Starch and Slowly Digestible Starch Values

In the procedure described here, the analytical time points of 20 and 120 min for the measurement of RDS and SDS are not intended to represent that time of passage through the human gut. The choice of 20 min of incubation for the measurement of RDS is based on observed rates of hydrolysis of starch in vitro. For foods in which starch is rapidly digested, such as bread and corn flakes, the majority of starch is digested by 20 min under the conditions described here, whereas a considerable amount of starch in foods such as spaghetti and pearled barley is digested between 20 and 120 min.

A recent study has shown a good correlation between glycemic index values from the literature and in vitro RAG values, which include RDS, and RAG is proposed as an important food-related determinant of the glycemic response.\(^{34}\)

More direct evidence for this was obtained when the glycemic response to four starchy foods with different proportions of RDS and SDS was investigated. Two of the foods, pearled barley and spaghetti, have a low proportion of starch as RDS, whereas corn flakes and white bread contain a high proportion of starch as RDS. The four foods were each fed in two portion sizes, providing 25 and 50 g of glucose (from RDS, SDS and FSG) likely to be available for absorption in the small intestine. The eight test meals represented a range of intake from 11 to 49 g of RAG. There was a very strong correlation (\(P < 0.001\)) between RAG intake and glycemic response, with RAG explaining 70% of the variance in glycemic response after subject variation was accounted for (Figure 3).\(^{19}\)

The results of this study and the good agreement between RAG and glycemic index strongly suggest that measurements of RAG and SAG, and the corresponding starch fractions, RDS and SDS, have physiological significance.\(^{19}\)

### 6.3 Validation of Resistant Starch Values

Quantifying the amount of starch entering the human colon presents a considerable technical problem. Hydrogen excreted in breath has been used as an indicator of fermentation in the colon, but it is considered to lack the sensitivity required for quantification. Intubation has been used to sample digesta from the ileum, but these studies were restricted to liquidized meals. Several studies have used human ileostomy subjects as a model to investigate the digestive physiology of the small intestine. Carbohydrate analysis of the ileostomy effluent allows determination of the amount of starch and starch digestion products escaping digestion in the small intestine.\(^{35-37}\) The amount of starch recovered in the ileostomy effluent varied between individuals by ±20% around the mean. It is from these studies that the currently accepted definition of RS is derived “the sum of starch and starch degradation products that, on average, reach the human large intestine”.\(^{16}\)

The in vitro methodology has been tuned to yield values for RS that match the mean proportion of starch recovered in ileostomy studies for both single foods and mixed meals.\(^{14,35-38}\)
7 COMPARISON WITH OTHER METHODS

7.1 Total Starch

A discussion of the principles of starch analysis has been provided by Southgate. Most methods for the measurement of TS are dependent on acid or enzymatic hydrolysis of starch and measurement of the released glucose. Generally, enzymatic approaches are more specific and do not result in destruction of sugars. Samples are usually finely divided and may be boiled to gelatinize starch before enzymatic hydrolysis with α-amylase and/or amyloglucosidase. However, retrograded amylose is not accessible to enzymatic hydrolysis before it has been dispersed with DMSO or 2-M KOH. Procedures that do not contain an efficient dispersal step will underestimate the starch content of some processed foods containing RS3. The values obtained by such methods will therefore be lower than those obtained by the method described here.

7.2 Rate and Extent of Starch Digestion

The increased knowledge of the different metabolic fates of dietary starch has resulted in the development of several methods for assessing the rate of starch digestion. The basis of the methods investigating the rate of starch digestion is the measurement of starch hydrolysis after a specified period of incubation with amylolytic enzymes. Meaningful comparison between methods is difficult, owing to differences in sample preparation, enzymes and hydrolysis conditions. However, the ranking between foods is often similar between methods, and most have shown strong correlations with glycemic response data. The RDS and SDS terms described here are at present the only measures of rate of starch digestion expressed in grams per 100 g of food.

The basis of methods for the determination of RS is the measurement of starch remaining unhydrolyzed after a defined period of incubation with amylolytic enzymes. Measurements of total RS must include RS1, RS2 and RS3. However, owing to inappropriate sample preparation and gelatinization of starch during the procedure, many methods measure only RS3 or RS2 and RS3 fractions. In addition, few of the methods have been developed and validated in conjunction with in vivo studies.

Methods designed to investigate the rate and/or the extent of starch digestion in the human gut should incorporate the following principles:

- analysis of foods prepared “as eaten”;
- reproducible disruption of the physical structure of food;
- standardized conditions of amylolytic hydrolysis;
- development and validation of methods in conjunction with in vivo studies.

The method described here is based on these principles, and incorporates in vitro measurements that reflect the likely rate and extent of starch digestion in the human gut.

3. M.J. Gidley, ‘Factors Affecting the Crystalline Type (A–C) of Native Starches and Model Compounds:

Viscosity of Food: Measurement and Application

M.A. Rao
Cornell University, Geneva, NY, USA

1 INTRODUCTION

The study of viscosity is but one aspect of rheology, which by definition is the study of deformation and flow of matter. The science of rheology grew considerably due to concurrent developments in polymer science, that in turn were necessary due to the many industrial uses of synthetic polymers. The rheological properties of foods are based on flow and deformation responses when subjected to stress. The word “texture” is generally associated with solid foods and is based on empirical tests using puncture, compression, and extrusion that are still specific to each food commodity. In most, if not all, instances the test geometries used in texture measurement are too complex for reliable mathematical analysis of the forces and strains involved.

Fluid foods containing relatively large amounts of dissolved low-molecular-weight compounds (e.g. sugars) and no significant amount of polymers or insoluble solids can be expected to exhibit Newtonian behavior:

- Newtonian foods – water, filtered depectinized juices, refined vegetable oils, sugar syrup, and wines;
- non-Newtonian foods – solutions of biopolymers (also called gums and hydrocolloids), chocolate, starch dispersions, baby foods and other puréed fruit and vegetable products, orange juice, tomato juice, paste and concentrate, mustard, mayonnaise, salad dressing, concentrated milk, and yoghurt.

A small amount (ca. 1%) of a dissolved polymer can substantially increase the viscosity of water and also alter the flow characteristics from Newtonian of water to non-Newtonian of the aqueous dispersion; although the rheological properties are altered substantially, the magnitudes of the thermal properties (e.g. density and thermal conductivity) of the dispersion remain relatively close to those of water. The techniques for measuring rheological properties, mathematical models for describing rheological behavior, and application to sensory assessment and handling/heating of foods have been reviewed by several authors. Here, they are covered in brief.

Shear rate, denoted by the symbol \( \dot{\gamma} \), is the velocity gradient established in a fluid as a result of a shear stress acting on it. It is expressed in units of reciprocal seconds. Shear stress is the stress component applied tangentially; it is equal to the force vector (a vector has both magnitude and direction) divided by the area of application and is expressed in units of force per unit area, pascals. The nomenclature committee of the Society of Rheology recommended that the symbol \( \sigma \) be used to denote shear stress. However, the symbol \( \tau \) that was used
to denote shear stress for a long time is often encountered in the literature.

Viscosity, is the internal friction of a fluid or its tendency to resist flow. It is denoted by the symbol \( \eta \) for Newtonian fluids, whose viscosity does not depend on the shear rate, and for non-Newtonian fluids to indicate shear rate dependence by \( \eta_a \). Depending on the flow system and choice of shear rate and shear stress, there are several equations to calculate the magnitude of \( \eta_a \). Here, it is defined by Equation (1):

\[
\eta_a = \frac{\text{shear stress}}{\text{shear rate}} = \frac{\sigma}{\dot{\gamma}}
\]

The preferred units of viscosity are Pa s or mPa s, but other units such as the centipoise (1 cP = 1 mPa s) can be found in the literature.

1.1 Newtonian and non-Newtonian Foods

1.1.1 Newtonian

A plot of shear rate versus shear stress can be used to classify flow behavior of foods (Figure 1). With Newtonian fluids, the shear rate is directly proportional to the shear stress and the plot begins at the origin. Typical Newtonian foods are those containing only low-molecular-weight compounds (e.g. sugars) and that do not contain large concentrations of either dissolved polymers (e.g. pectins, proteins, starches) or insoluble solids. For example, water, sugar syrups, most honeys, most carbonated beverages, edible oils, filtered juices, and milk are Newtonian fluids.

All other types of fluid foods are non-Newtonian which means that either the shear stress–shear rate plot is not linear and/or the plot does not begin at the origin, or the material exhibits time-dependent rheological behavior as a result of structural changes. Flow behavior may depend only on shear rate and not on the duration of shear (time-independent) or may depend also on the duration of shear (time-dependent). Several types of time-independent flow behavior of foods have been encountered.

1.1.2 Shear Thinning

With shear-thinning fluids, the curve begins at the origin of the shear stress–shear rate plot but is concave upwards, i.e. an increasing shear rate gives a less than proportional increase in shear stress. Shear-thinning fluids are popularly called pseudoplastic. The term “shear thinning” is preferred because it is an accurate description of the shear rate–shear stress curve. Shear thinning may be thought of being due to the breakdown of structural units in a food due to the hydrodynamic forces generated during shear. Most non-Newtonian foods exhibit shear-thinning behavior, including many mayonnaises, salad dressings, and some concentrated fruit juices as well as puréed fruits and vegetables.

1.1.3 Yield Stress

The flow of some materials may not commence until a threshold value of stress, the yield stress \( (\sigma_0) \), is exceeded. Shear thinning with yield stress behavior is exhibited by foods, such as tomato concentrates, tomato ketchup, mustard, and mayonnaise. In the event, the shear rate–shear stress data follow a straight line with a yield stress, the food is said to follow the Bingham plastic model.

1.1.4 Shear Thickening

In shear-thickening behavior also, the curve begins at the origin of the shear stress–shear rate plot and is concave downwards, i.e. an increasing shear stress gives a less than proportional increase in shear rate. This type of flow has been encountered in partially gelatinized starch dispersions. The term “dilatant” is popularly and incorrectly used to describe shear thickening. Because dilatancy implies an increase in the volume of the sample during the test, it is incorrect to use it to describe shear-thickening rheological behavior. Strictly speaking, shear-thickening should be due to increase in the size of the structural units as a result of shear.

1.2 Description of Time-independent Flow Behavior

A flow model may be considered to be a mathematical equation that can describe rheological data, such as shear rate–shear stress data in a basic shear diagram; it provides a convenient and concise manner of describing the data.
Occasionally, such as for the viscosity versus temperature data during starch gelatinization, more than one equation may be necessary to describe the rheological data.

### 1.2.1 Newtonian Model

The model for a Newtonian fluid is described by Equation (2):

$$\sigma = \eta \dot{\gamma}$$  \hspace{1cm} (2)

From the definition of a Newtonian fluid, the shear stress and the shear rate are proportional to each other, and a single parameter $\eta$ characterizes the data. For a Bingham plastic fluid that exhibits a yield stress ($\sigma_0$), the model is

$$\sigma - \sigma_0 = \eta' \dot{\gamma}$$  \hspace{1cm} (3)

where in Equation (3) $\eta'$ is called the Bingham plastic viscosity.

As shown in Figure 1, the Newtonian model and the Bingham plastic model can be illustrated by straight lines in terms of shear rate and shear stress, and the former can be described by one parameter $\eta$ and the latter by the two parameters $\eta'$ and $\sigma_0$. However, the shear rate–shear stress data of shear-thinning and shear-thickening fluids are curves that require more than one parameter to describe their data. Because the equation of a straight line is simple in that it can be described by just two parameters (the slope and the intercept) shear rate–shear stress data are often transformed in to such lines.

### 1.2.2 Power Law Model

Shear stress–shear rate plots of many fluids become linear when plotted on double logarithmic coordinates and the power law model describes the data of shear-thinning and shear thickening fluids (Equation 4):

$$\sigma = KH \dot{\gamma}^n$$  \hspace{1cm} (4)

where $K$, the consistency index (Pa s$^n$), is the shear stress at a shear rate of 1.0 s$^{-1}$ and the exponent $n$, the flow behavior index, is dimensionless that also reflects the closeness to Newtonian flow. For the special case of a Newtonian fluid ($n = 1$), the consistency index $K$ is identically equal to the viscosity of the fluid. When the magnitude of $n < 1$ the fluid is shear thinning and when $n > 1$ the fluid is shear thickening in nature. Taking logarithms of both sides of Equation (4),

$$\log \sigma = \log K + n \log \dot{\gamma}$$  \hspace{1cm} (5)

In Equation (5) the parameters $K$ and $n$ are determined from a plot of $\log \sigma$ versus $\log \dot{\gamma}$, and the resulting straight-line intercept is $\log K$ and the slope is $n$. If a large number (e.g. >15) of $\sigma, \dot{\gamma}$ data points are available (it is easy to obtain a large number of points with automated viscometers), linear regression of $\log \dot{\gamma}$ versus $\log \sigma$ will provide statistically best values of $K$ and $n$. Nevertheless, a plot of experimental and predicted values of $\log \dot{\gamma}$ and $\log \sigma$ is useful for observing trends in data and ability of the model to follow the data. Linear regression techniques can also be used for determination of the parameters of the Herschel–Bulkley (when the magnitude of the yield stress is known) and the Casson models, discussed later.

Because it contains only the two parameters $K$ and $n$, the power law model has been used extensively to characterize fluid foods, and in studies on handling and heating/cooling of foods. Extensive compilations of the magnitudes of power law parameters can be found in Holdsworth (1) and Rao (2). Because it is convenient to group foods into commodities, Rao (2) compiled the magnitudes of power law parameters of food commodities. In addition, the influence of temperature in quantitative terms of activation energies, and the effect of concentration of soluble and insoluble solids on the consistency index are given.

Although the power law model is popular and useful, its empirical nature should be noted. Another reason for its popularity results from its applicability over the shear rate range $10^4$–$10^8$ s$^{-1}$ that can be obtained in many commercial viscometers. Often, the magnitudes of the consistency and the flow behavior indexes of a food sample depend on the specific shear rate range being used so that when comparing the properties of different samples an attempt should be made to determine $K$ and $n$ over a specific range of shear rates.

One drawback of the power law model is that it does not describe the low-shear and high-shear rate constant-viscosity data of shear-thinning foods where limiting zero-shear ($\eta_0$) and infinite-shear viscosities ($\eta_{\infty}$) are reached, respectively. The models of Cross and Carreau were capable of describing apparent viscosity versus shear rate data over the entire ranges of data obtained on food polymer dispersions. (2) Very low shear rates (ca. $10^{-3}$ s$^{-1}$) are necessary to obtain reliable values of $\eta_0$.

### 1.2.3 Herschel–Bulkley Model

When yield stress of a food is measurable, it can be included in the power law model and the model is known as the Herschel–Bulkley model (Equation 6):

$$\sigma - \sigma_0 =KH(\dot{\gamma})^{n_1}$$  \hspace{1cm} (6)

where $\dot{\gamma}$ is the shear rate (s$^{-1}$), $\sigma$ is shear stress (Pa), $n_1$ is the flow behavior index, $K_H$ is the consistency index, and $\sigma_0$ is the yield stress. The concept of yield stress has been challenged by Barnes and Walters (3) because a fluid may deform minutely at stress values lower than the yield stress. Nevertheless, yield stress may be considered to
be an engineering reality and plays an important role in many food products.

If the yield stress of a sample is known from an independent experiment, \( K_{II} \) and \( n_{II} \) can be determined from linear regression of \( \log(\sigma - \sigma_0) \) versus \( \log(\gamma) \) as the intercept and slope, respectively. Alternatively, nonlinear regression techniques can be used to estimate \( \sigma_0 \), \( K_{II} \), and \( n_{II} \) of tomato concentrates.\(^4\) However, estimated values of yield stress and other rheological parameters should be used only when experimentally determined values are not available.

### 1.2.4 Casson Model

The Casson\(^5\) model (Equation 7) is a structure-based model that, although originally developed for characterizing printing inks, has been used for a number of food dispersions:

\[
\sigma^{0.5} = K_{hc} + K_c(\gamma)^{0.5} \tag{7}
\]

For a food following the Casson model, a straight line results when the square root of shear rate, \( (\gamma)^{0.5} \), is plotted against the square root of shear stress, \( (\sigma)^{0.5} \), with slope \( K_c \) and intercept \( K_{hc} \). The Casson yield stress is calculated as the square of the intercept, \( \sigma_{hc} = (K_{hc})^2 \) and the Casson plastic viscosity as the square of the slope, \( \eta_{ca} = (K_c)^2 \). The International Office of Cocoa and Chocolate has adopted the Casson model as the official method for interpretation of flow data on chocolate samples. The Casson plastic viscosity can be used as being equivalent to the infinite shear viscosity (\( \eta_{\infty} \)) of dispersions by considering the limiting viscosity at infinite shear rate.\(^2\)

### 1.3 Time-dependent Behavior

Foods that exhibit time-dependent shear-thinning behavior are said to exhibit thixotropic flow behavior. Most of the foods that exhibit thixotropic behavior are heterogeneous systems containing a dispersed phase containing small particles. At rest, the particles or molecules in the food are linked together by weak forces. When the hydrodynamic forces during shear are sufficiently high, the interparticle linkages are broken, resulting in reduction in the size of the structural units that in turn offer lower resistance to flow during shear. This type of behavior is common to foods such as salad dressings and soft cheeses where the structural adjustments take place in the food due to shear until an equilibrium is reached.

Time-dependent shear-thickening behavior, formerly called rheopectic behavior, is called antithixotropic behavior. This type of behavior, although rare, is being detected in many foods due to the development of sensitive automated rheometers. When shear rate versus shear stress data are obtained first in ascending order of shear rate and immediately afterwards in descending order, the two curves will not coincide and values of the latter will be lower than the former for thixotropic foods. Repetition of the experiments will result in an equilibrium hysteresis loop.

In antithixotropic behavior, the shear stress values in descending order of shear rates are higher than those in ascending order. The primary difficulty in obtaining reliable thixotropic or antithixotropic data is that during loading of the test sample in to a measurement geometry structural changes occur that cannot be either controlled or expressed quantitatively. Therefore, considerable caution should be exercised in using the area of hysteresis loop as a measure of thixotropic behavior and a characteristic of the food.

### 1.4 Effect of Soluble and Insoluble Solids Concentration on Apparent Viscosity of Foods

#### 1.4.1 Intrinsic Viscosity

The effect of concentration on the Newtonian or zero-shear viscosity of biopolymer dispersions can be expressed in terms of the coil overlap parameter \( c[n] \), where \( c \) is the concentration of the polymer and \( [n] \) is the intrinsic viscosity of the polymer in a specific solvent.

Many foods contain high-molecular-weight polymers, such as proteins, pectins, and others. Often, they contribute significantly to the structure and viscosity of foods. In dilute solutions, the polymer chains are separate and the intrinsic viscosity, denoted as \( \eta = [n] \), of a polymer in solution depends only on the dimensions of the polymer chain. Because \([n]\) indicates the hydrodynamic volume of the polymer molecule and is related to the molecular weight and to the radius of gyration, it reflects important molecular characteristics of a biopolymer. The concentrations of polymers used should be such that the relative viscosities \( (\eta/\eta_s) \) of the dispersions are from about 1.2 to 2.0 to ensure good accuracy and linearity of extrapolation to zero concentration.\(^6\)\(^7\) Intrinsic viscosity can be determined from dilute solution viscosity data as the zero concentration limit of specific viscosity \( \eta_s \) divided by concentration \( c \) (Equation 8):

\[
[n] = \lim_{c \to 0} \frac{\eta_s}{c} \tag{8}
\]

where \( \eta_s = [(\eta - \eta_s)/\eta_s] \), and \( \eta \) and \( \eta_s \) are the viscosities of the solution and the solvent, respectively. When a dilute solution exhibits shear-thinning behavior, its zero shear viscosity, \( \eta_0 \), at very low shear rates (vanishing shear rates) may be used in place of the Newtonian viscosity \( \eta \). There are several ways of determining the intrinsic viscosity \([n]\) from experimental dilute solution viscosity data.\(^8\) The two equations commonly employed
for determining \([n]\) of food gums are those of Huggins (Equation 9) and Kraemer (Equation 10):

\[
\frac{\eta_{sp}}{c} = [n] + k_1[n]^2c
\]  

(Equation 9)

\[
\frac{\ln(n_t)}{c} = [n] + k_2[n]^2c
\]  

(Equation 10)

In Equation 10, \(n_t\) is the relative viscosity (\(\eta/\eta_v\)). Equations (9) and (10) imply that plots of \(\eta_{sp}/c\) versus \(c\) and \(\ln(n_t)/c\) versus \(c\) would result in straight lines, respectively. To obtain reliable values of intrinsic viscosity, the extrapolations are usually done for relative viscosity values between 1.2 and 2.0 when the corresponding specific viscosities are between about 0.2 and 1.0. The Huggins constant \(k_1\) is considered to be an index of the polymer–polymer interaction with a large number of the reported values being between 0.3 in good solvents and 1.0 in theta solvents; the higher values are attributed to the existence of association between the macromolecules. The Huggins and Kraemer constants \((k_1\) and \(k_2\)) are theoretically related by Equation (11):

\[
k_1 = k_2 + 0.5
\]  

(Equation 11)

The Huggins equation has been used more extensively than the Kraemer equation. For polyelectrolytes (charged polymers), Tam and Tiu\(^{(9)}\) utilized the equation of Fuoss–Strauss (Equation 12):

\[
\frac{\eta_{sp}}{c} = \frac{[n]}{(1 + Bc^{1/2})}
\]  

(Equation 12)

When \((c/\eta_{sp})\) is plotted against \(c^{1/2}\), a straight line is obtained with an intercept of \(1/[n]\) and a slope of \(B/[n]\). The Mark–Houwink empirical equation relates intrinsic viscosity and the average molecular weight \(M\) (Equation 13):

\[
[n] = K(M)^a
\]  

(Equation 13)

where \(K\) and \(a\) are constants at a specific temperature for a given polymer–solvent system. The magnitude of the constant \(a\) is generally in the range 0.5–0.8 when conformation of the polymer is random coil.\(^{(10)}\) For polymers that assume compact conformations, the magnitudes of the exponent \(a\) are lower than 0.5. Magnitudes of the constant \(a\) higher than 0.8 are encountered when hydrodynamic interactions are absent (free draining random coil), i.e. when the solvent can drain freely between the macromolecules, as is the case when the conformations are elongated and rigid (rod-like polymers). A large number of models have been used to deduce intrinsic viscosity–molecular weight relationships,\(^{(10)}\) including the equivalent-sphere model (Flory–Fox equation), the random-flight model for flexible chain molecules, the worm-like chain model, and rigid elongated molecules. Rigid elongated conformations have been associated with large values of the Mark–Houwink exponent, with values of 1.7–1.8 being reported for some polyelectrolytes at low ionic strength and high degrees of dissociation. The magnitudes of intrinsic viscosity and of molecular weight of several biopolymers are available\(^{(2)}\) significant differences in the magnitudes are encountered depending on the structural characteristics, such as molecular mass (length of the chain) and different degrees of substitution. For polymers with charges, both the magnitude of \([n]\) and the rheological behavior are also affected by the pH and the ionic strength of the solution; therefore, their values should be controlled in studies of \([n]\) and their rheological behavior.

1.5 Effect of Biopolymer Concentration on Zero-shear Viscosity

In earlier studies on solutions of synthetic polymer melts,\(^{(11)}\) the zero-shear viscosity was found to be related to the molecular weight of the polymers. Plots of \(\log \eta\) versus \(\log M\) often resulted in two straight lines with the lower-\(M\) section having a slope of about 1.0 and the upper-\(M\) section having a slope of about 3.4. Because the apparent viscosity also increases with concentration of a specific polymer, the roles of both molecular size and concentration of polymer need to be understood. In polymer dispersions of moderate concentration, the viscosity is controlled primarily by the extent to which the polymer chains interpenetrate that is characterized by the coil overlap parameter \(c/[n]\).\(^{(12)}\) The product \(c/[n]\) is dimensionless and indicates the volume occupied by the polymer molecule in the solution.

A plot of \(\log c/[n]\) against \(\log ([\eta_0] - [n])/[n]\) of several food gum solutions at 25 °C adapted from Morris et al.\(^{(13)}\) is shown in Figure 2. In Figure 2, there are two regions: a region of dilute dispersions where the viscosity dependence on concentration follows a 1.4 power, and a region of concentrated dispersions where the viscosity dependence on concentration follows a 3.3 power. The transition from the dilute to the concentrated region occurred at a value of \(c/[n] = 4.0\). However, data on a few biopolymers (e.g. guar gum and locust bean gum) were found to deviate from the above observations. First, the region of concentrated solution behavior began at lower values of the coil overlap parameter \(c/[n] = 2.5\). Second, the viscosity showed a higher dependence on concentration with a slope of 5.1 instead of about 3.3. These deviations were attributed to specific intermolecular associations (hyperentanglements) between regular and rigid chain sequences in addition to the simple process of interpretation. Launay et al.\(^{(10)}\) suggested that there could be two transitions, instead of one transition shown in Figure 2,
Figure 2 Plot of log coil overlap parameter \((c[n])\) versus log\([\eta_0 - \eta_i]/\eta_i\) of several biopolymer dispersions; \(\eta_0\) is zero shear viscosity and \(\eta_i\) is viscosity of the solvent at 25 °C. (Reproduced with permission from M.A. Rao, ‘Engineering Properties of Foods: Current Status’, in Food Engineering 2000, eds. P. Fito, E. Oreiga Rodriguez, G. Barbosa-Cánovas, Aspen Publishers Inc., Gaithersburg MD, 39–54.)

before the onset of high concentration–viscosity behavior. Because intrinsic viscosity of a biopolymer can be determined with relative ease, Figure 2 can be used to estimate the polymer’s zero-shear viscosity of any food polymer at a specific polymer concentration at 25 °C.

Unlike biopolymer dispersions where the intrinsic viscosity is known and the concentration can be chosen a priori, often for fluid foods the concentration of soluble (e.g. pectins in fruit juices) and insoluble solids can be determined only posteriori, and the determination of their zero-shear viscosities is also difficult due to instrument limitation and the existence of yield stress. In most foods, often it is possible to identify the component(s), called key component(s) that play an important role in the rheological properties.\(^{(2)}\) The effect of concentration \(c\) of soluble or insoluble solids on either apparent viscosity \(\eta_a\) or the consistency index of the power law model \(K\) can be described by either exponential or power law relationships (Equations 14–17):

\[
\eta_a \propto \exp(ac) \tag{14}
\]

\[
\eta_a \propto c^b \tag{15}
\]

\[
K \propto \exp(a'c) \tag{16}
\]

\[
K \propto c^{b'} \tag{17}
\]

where \(a, a', b\) and \(b'\) are constants to be determined from experimental data. For example, the effect of concentration \(c\) of soluble solids \((°\text{Brix})\) and insoluble solids (pulp) on either apparent viscosity or the consistency index of the power law model of concentrated orange juice (COJ)

can be described by exponential relationships.\(^{(14,15)}\) In the case of COJ, it should be noted that insoluble solids are expressed in terms of pulp content determined on a 12 °Brix sample by centrifugation for 10 min at 360 × g (Equations 18 and 19):

\[
K = K^c \exp(B^c_k \times \text{Brix}) \tag{18}
\]

\[
K = K^p \exp(B^p_k \times \text{pulp}) \tag{19}
\]

where \(K^c, K^p, B^c_k,\) and \(B^p_k\) are constants. The role of insoluble solids can be also studied in terms of the relative viscosity, \(\eta_i = (\text{apparent viscosity of COJ/apparent viscosity of serum})\), and pulp fraction and, as expected, such a plot has the limiting value of 1.0 at zero pulp fraction (serum).\(^{(2)}\)

1.6 Food Dispersions

When dispersions contain insoluble particles of nearly uniform size, their viscosity can be expressed in terms of the Peclet number.\(^{(16,17)}\) Yoo and Rao\(^{(18)}\) showed that the influence of two different sizes of tomato pulp particles (TP4 and TP6) at a pulp weight fraction of 17% could be described in terms of Peclet number and relative viscosity (Figure 3). Magnitudes of the Peclet numbers (Pe) were calculated using Equation (20):

\[
Pe = \frac{\eta_0 r_0^2 \gamma}{kT} \tag{20}
\]

where \(\eta_0\) is the viscosity of the suspending liquid (serum), \(r_0\) is the particle radius, \(k\) is the Boltzmann constant.

Figure 3 Peclet number versus relative viscosity of tomato pulp particles. At equal values of pulp weight fraction, a TP6 sample with small diameter particles was more viscous than a TP4 sample with large diameter particles. (Reproduced by permission of Food and Nutrition Press, Inc., from Yoo and Rao\(^{(18)}\)).
The viscosity of food systems is a critical property that influences the behavior of food products during processing, storage, and consumption. Variations in temperature, concentration of food components, and the presence of dispersed particles all affect the viscosity of food systems. Understanding the factors that influence viscosity allows for the development of products with desired rheological properties.

1.7 Effect of Temperature on Viscosity

A wide range of temperatures is encountered during processing and storage of fluid foods, so that the effect of temperature on rheological properties needs to be described quantitatively. The effect of temperature on the viscosity of Newtonian fluids, or on either the apparent viscosity at a specified shear rate or the consistency index $K$ of the power law model of a fluid can be described often by the Arrhenius relationship. For the apparent viscosity, the Arrhenius relationship is written as Equation (21):

$$\eta_a = \eta_{\infty A} \exp \left( \frac{E_a}{RT} \right)$$

where $\eta_a$ is the apparent viscosity at a specific shear rate, $\eta_{\infty A}$ is the frequency factor, $E_a$ is the activation energy (J mol$^{-1}$), $R$ is the gas constant (J mol$^{-1}$ K$^{-1}$), and $T$ is the temperature (K).

The quantity $E_a$ is the energy barrier that must be overcome before the elementary flow process can occur and $E_a$ is the activation energy for viscous flow. From the slope of a plot of $\ln \eta_a$ (ordinate) versus $(1/T)$ (abscissa), $E_a$ can be calculated as (slope $\times R$); we note that $\eta_{\infty A}$ is the exponential of the intercept. The Arrhenius equation for the consistency index is (Equation 22)

$$K = K_{\infty} \exp \left( \frac{E_{ak}}{RT} \right)$$

where $K_{\infty}$ is the frequency factor, $E_{ak}$ is the activation energy (J mol$^{-1}$), $R$ is the gas constant, and $T$ is the temperature (K). A plot of $\ln K$ (ordinate) versus $(1/T)$ (abscissa) results in a straight line, and $E_{ak} = \text{(slope} \times R)$, and $K_{\infty}$ is the exponential of the intercept. Although the activation energy should be expressed in joules, it is often expressed in calories (1 cal = 4.1868 J). The applicability of the Arrhenius model to the apparent viscosity versus temperature relationship is shown in Figure 4.

$\eta_{\infty A}$ is the consistency index of orange juice. A plot of $\eta_{\infty A}$ versus $1/T$ results in a straight line, and $E_{ak} = \text{(slope} \times R)$, and $\eta_{\infty A}$ is the exponential of the intercept. Although the activation energy should be expressed in joules, it is often expressed in calories (1 cal = 4.1868 J). The applicability of the Arrhenius model to the apparent viscosity versus temperature relationship is shown in Figure 4.
temperature data on a COJ serum sample\textsuperscript{(14,15)} is shown in Figure 4.

The Arrhenius equation did not describe very well the influence of temperature on viscosity data of concentrated apple and grape juices in the range 60–68 °Brix\textsuperscript{(22,23)}.

It was determined that the empirical Fulcher equation (see Ferry\textsuperscript{(11)} p. 289, and Soesanto and Williams\textsuperscript{(24)}) described the viscosity versus temperature data on those juice samples better than the Arrhenius model\textsuperscript{(23)}:

\[
\log \eta = A' + \frac{B'}{T - T_\infty}
\]  

(23)

where in Equation (23) $A'$ and $B'$ are constants.

2 MEASUREMENT OF VISCOSITY AND RHEOLOGICAL BEHAVIOR

A well-designed viscometer must be capable of providing readings that can be converted to shear rate and shear stress. In addition, it should allow for the recording of the readings so that time-dependent flow behavior can be studied. The shear stresses that need to be measured in the case of low-viscosity foods are low in magnitudes so that instruments that minimize friction by the use of gas bearings are very useful. The flow in the selected geometry should be steady, laminar and fully developed, and the temperature of the test fluid should be maintained uniform. For obtaining data under isothermal conditions the temperature of the sample should be maintained constant at the desired level.

2.1 Viscometer Geometries

For foods that exhibit Newtonian behavior, viscometers that operate at a single shear rate (e.g. glass capillary) are acceptable. A glass capillary viscometer is shown in Figure 5. A test sample is loaded to mark E by first inverting the viscometer, immersing tube A in the sample, and applying suction to tube G. After the sample had attained the desired temperature in a bath, suction is applied to tube A so that the test liquid is drawn above mark C. The efflux time $t$ for the liquid to pass from mark C to mark E is noted and used to calculate the viscosity using calibration constants provided by the manufacturer. Alternatively, the elapsed times for a test liquid $t$ and a standard liquid $t_{st}$ of the same density to flow between two etched lines are determined. Because the magnitude of viscosity is directly proportional to the time of flow, the viscosity of a fluid can be calculated as Equation (24):

\[
\eta = \left( \frac{t}{t_{st}} \right) \eta_{st}
\]  

(24)

The magnitudes of $t$ and $t_{st}$ must be determined with care at a specific temperature, and the magnitude of viscosity of the standard fluid $\eta_{st}$ must be reliable. Glass capillary viscometers are not suitable for liquids that deviate substantially from Newtonian flow or contain large-size particles or a high concentration of suspended solids.
For foods that exhibit non-Newtonian behavior, data should be obtained at several shear rates and the commonly used viscometric flow geometries in rheological studies on foods include: (a) concentric cylinder (Figure 6), (b) plate and cone (cone-plate; Figure 7), (c) parallel disk (also called parallel plate), (d) capillary/tube/pipe, and (e) slit flow. The relationships for shear stress for flow in capillary/tube and slit geometries can be deduced relatively easily from the pressure drop over a fixed length after fully developed flow has been achieved. Likewise, in concentric cylinder, cone-plate, parallel disk geometries, the shear stress can be calculated from the measured torque and the dimensions of the test geometry being used. In contrast, the derivation of expressions for the shear rate requires solution of the continuity and momentum equations with the applicable boundary conditions can be found in several texts, such as Whorlow and Rao, and will not be covered here.

Further, modern commercial viscometers/rheometers are automated so that the shear rate and shear stress are calculated by a computer. It is noted that in a properly designed cone-plate geometry the shear rate depends only on the rotational speed and not on the geometrical characteristics. In all other flow geometries, the dimensions of the measuring geometry (capillary, concentric cylinder, parallel disks) play important roles. Because the concentric cylinder and the plate-cone geometries are encountered commonly, the equations for shear stress and Newtonian shear rate are given.

2.1.1 Concentric Cylinder Viscometer

In a concentric cylinder geometry, the shear stress can be determined from the total torque $M$ (Equation 25):

$$\sigma = \frac{M}{2\pi r_i^2 h}$$  \hspace{1cm} (25)

where $r_i$ is the radius of the rotating bob. The Newtonian shear rate in a concentric cylinder geometry can be calculated exactly from Equation (26):

$$\dot{\gamma}_N = \frac{2\Omega_o^2}{\left[1/r_i^2 - 1/r_o^2\right]} = \frac{2\Omega}{\left[1 - (r_i/r_o)^2\right]}$$  \hspace{1cm} (26)

where $\Omega$ is the angular velocity of the rotating bob, $r_i$ is the radius of the bob, and $r_o$ is the radius of the cup. Recalling that viscosity is obtained by dividing the magnitude of shear stress by the corresponding shear rate, the viscosity of a Newtonian fluid from concentric cylinder flow data is given by the Margules Equation (27):

$$\eta = \left(\frac{M}{4\pi \Omega h}\right) \left(\frac{1}{r_i^2} - \frac{1}{r_o^2}\right)$$  \hspace{1cm} (27)

2.1.2 Cone-plate Viscometer

The shear rate and shear stress are given by Equations (28) and (29):

$$\text{shear stress, } \sigma = \frac{3T_c}{D}$$  \hspace{1cm} (28)

$$\text{shear rate, } \dot{\gamma} = \frac{\Omega}{\theta}$$  \hspace{1cm} (29)

where $T_c$ is the torque per unit area, $D$ is the diameter of the rotating cone or plate, $\Omega$ is the angular velocity, and $\theta$ is the cone angle in radians. In general, $\theta$ is usually quite small ($2\text{–}4^\circ$).

2.2 Measurement of Viscoelastic Behavior of Fluid Foods

Viscometric functions are generally used to relate stress with shear rate in liquid systems, whereas elastic functions are related to the appropriate stress function to strain in solids. Viscoelastic properties cover the combination where a material exhibits both viscous and elastic properties. The relationships between stress and strain, and the influence of time on them, are generally described by constitutive equations or rheological equations of state. When the strains are relatively small, i.e. in the linear range, the constitutive equations are relatively simple. In the linear viscoelastic range, one can express a large linear deformation as the sum of all the small linear deformations.

Viscoelastic behavior of many foods has been studied by means of dynamic shear, creep compliance, and stress relaxation techniques. The paradigm shift from emphasis on normal stress measurements to dynamic rheological technique took place gradually, beginning in the late 1950s. It is customary to employ different symbols for the various rheological parameters in different types of deformation – shear, bulk, or simple – and the symbols...
where \( G \) at time \( t \) should be equivalent to data from a transient experiment amplitude ratio are measured. The information obtained between the oscillating stress and strain as well as the \( G \) according to Equation (25) and the phase difference \( \tan \delta \) components in the viscoelastic material: an elastic phase viscous component. Equations (31–33), that define viscoelastic behavior, can be derived:

\[
\begin{align*}
G' &= \frac{\sigma_0}{\gamma_0} \cos \delta \\
G'' &= \frac{\sigma_0}{\gamma_0} \sin \delta \\
\tan \delta &= \frac{G''}{G'}
\end{align*}
\]

where \( G' \) (Pa) is the storage modulus, \( G'' \) (Pa) is the loss modulus, and \( \tan \delta \) is the loss tangent.

The storage modulus \( G' \) expresses the magnitude of the energy that is stored in the material or recoverable per cycle of deformation; \( G'' \) is a measure of the energy that is lost as viscous dissipation per cycle of deformation. Therefore, for a perfectly elastic solid, all the energy is stored, i.e. \( G'' \) is zero and the stress and the strain will be in phase. In contrast, for a liquid with no elastic properties all the energy is dissipated as heat, i.e. \( G' \) is zero and the stress and the strain will be out of phase by 90° (Figure 8).

For a specific food, magnitudes of \( G' \) and \( G'' \) are influenced by frequency, temperature, and strain. For strain values within the linear range of deformation, \( G' \) and \( G'' \) are independent of strain. The loss tangent, is the ratio of the energy dissipated to that stored per cycle of deformation. These viscoelastic functions have been found to play important roles in the rheology of structured polysaccharides. One can also employ notation using complex variables and define a complex modulus \( G^*(w) \) (Equation 34):

\[
|G^*| = \sqrt{(G')^2 + (G'')^2}
\]

We note that the dynamic viscosity and the dynamic rigidity are components of the complex dynamic

2.2.1 Oscillatory Shear Flow

Small amplitude oscillatory shear (SAOS), also called dynamic rheological experiment, can be used to determine viscoelastic properties of foods. The experiments can be conducted with the Couette, plate and cone, and parallel plate geometries. As noted earlier, uniform shear is achieved in the gap of a cone-plate geometry. However, the narrow gap may not be suitable for studying foods containing solids with dimensions greater than about 100 μm. In the SAOS tests, a food sample is subjected to a small sinusoidally oscillating strain or deformation \( \gamma(t) \) at time \( t \) according to Equation (25) and the phase difference between the oscillating stress and strain as well as the amplitude ratio are measured. The information obtained should be equivalent to data from a transient experiment at time \( t = w^{-1} \) (Equation 30)

\[
\gamma(t) = \gamma_0 \sin(wt)
\]

where \( \gamma_0 \) is the strain amplitude and \( w \) the angular frequency. The applied strain generates two stress components in the viscoelastic material: an elastic component in line with the strain and a 90° out of phase viscous component. Equations (31–33), that define viscoelastic behavior, can be derived:

\[
\begin{align*}
G' &= \frac{\sigma_0}{\gamma_0} \cos \delta \\
G'' &= \frac{\sigma_0}{\gamma_0} \sin \delta \\
\tan \delta &= \frac{G''}{G'}
\end{align*}
\]

Illustration of strain and stress profiles in dynamic tests. When the strain is the stimulus, the stress is the response and both are recorded.
It should be noted that if $G'$ is much greater than $G''$, the material will behave more like a solid, i.e. the deformations will be essentially elastic or recoverable. However, if $G'$ is much greater than $G''$ the energy used to deform the material is dissipated viscously and the material's behavior is liquid like. The viscoelastic moduli determined over a range of frequencies will indicate materials behavior is liquid like. The viscoelastic moduli to deform the material is dissipated viscously and the imaginary part $\eta''$ is equal to $(G''/\omega)$ and the real part $\eta'$ is equal to $(G'/\omega)$. One can also determine the loss modulus $G''$, from oscillatory shear data using Equation (36):

$$G'' = \omega \eta'$$

(36)

It should be noted that if $G'$ is much greater than $G''$, the real part of the complex viscosity $\eta'$ is equal to $(G'/\omega)$ and the imaginary part $\eta''$ is equal to $(G''/\omega)$. One can also determine the loss modulus $G''$, from oscillatory shear data using Equation (36): 

$$G'' = \omega \eta'$$

(36)

2.2.2 Types of Dynamic Rheological Tests

Dynamic rheological experiments provide suitable means for monitoring the gelation process of many biopolymers and for obtaining insight into gel/food structure because they satisfy several conditions.$^{(26, 27)}$

- they are nondestructive and do not interfere with either gel formation or softening of a structure;
- the time involved in the measurements is short relative to the characteristic times of the gelation and softening processes;
- the results are expressible in fundamental terms so that they can be related to the structure of the network.

For the same reasons, they were used to follow the changes induced on potato cells by cellulase,$^{(28)}$ $\alpha$-amylase on wheat starch,$^{(27)}$ and can be used in studying other phase transitions in foods.

A strain sweep in which the strain is varied over a range of values is an essential test to determine the linear viscoelastic range. With controlled stress rheometers, a stress sweep can be conducted. The limit of linearity can be detected when dynamic rheological properties (e.g. $G'$ and $G''$) change rapidly from their almost constant values. Three other types of dynamic rheological tests can be conducted to obtain useful properties of viscoelastic foods, such as gels, and of gelation and melting:

- Frequency sweep studies in which $G'$ and $G''$ are determined as a function of frequency $\omega$ at a fixed temperature.
- Temperature sweep studies in which $G'$ and $G''$ are determined as a function of temperature at fixed $\omega$. This test is well suited for studying gel formation during cooling of a heated polymer (e.g. pectin, gelatin) dispersion,$^{(29)}$ gelatinization of a starch dispersion during heating,$^{(30)}$ and gel formation of proteins.$^{(31)}$
- Time sweep study in which $G'$ and $G''$ are determined as a function of time at fixed $\omega$ and temperature. This type of test, often called a gel cure experiment, is well suited for studying structure development in physical gels.

2.3 Relationships Between Steady Shear and Oscillatory Shear Parameters

The relationship between the rheological parameters determined from oscillatory tests such as $\eta^*$ and $\eta'$ on one hand and the apparent viscosity (from shear stress and shear rate) on the other is of interest. The superimposition of the shear rate dependence of steady shear viscosity $\eta_a$, and of the frequency dependence of the complex viscosity $\eta^*$, at equal values of frequency and shear rate, was first reported by Cox and Merz$^{(32)}$ for polystyrene samples, and is known as the Cox–Merz rule (Equation 37):

$$\eta^*(\omega) = \eta_a(\omega)|_{\gamma = \gamma'}$$

(37)

This empirical correlation has been confirmed experimentally for several synthetic polymers,$^{(11)}$ and for several solutions of random-coil polysaccharides.$^{(33)}$ However, many exceptions to the Cox–Merz rule have also been found for synthetic polymers$^{(34)}$ as well as for biopolymer systems and foods.$^{(5)}$ Relationships between the parameters were determined for equal magnitudes of the shear rate $\gamma$ and the frequency $\omega$.$^{(35)}$ Based on data on 10 fluid and semisolid foods, power-type relationships were found to be satisfactory between the parameters (Equations 38 and 39):

$$\eta^*(\omega) = C[\eta(\gamma)]^a|_{\gamma = \gamma'}$$

(38)

$$\eta'(\omega) = C[\eta(\gamma)]^a|_{\gamma = \gamma'}$$

(39)

Similarly, a power-type equation related $G'/\omega^2$ and the first normal stress coefficient $\Psi_1$ (Equation 40):

$$\frac{G'}{\omega^2(\omega)} = C[\Psi_1(\gamma)]^a$$

(40)

Deviation from the Cox–Merz rule appears to be an indication of structural heterogeneities in a food. For example, significant deviations from the Cox–Merz rule were found in dispersed systems, such as tomato
FOOD

concentrates\(^{(36)}\) and cross-linked waxy maize starch dispersions.\(^{(37)}\) In contrast, the Cox–Merz rule was found to be applicable to fluids with homogeneous structures, such as dispersions of guar gum and locust bean gum.

When departures from the Cox–Merz rule are attributed to structure decay in the case of steady shear, the complex viscosity is usually larger than the steady viscosity.\(^{(2)}\) Nevertheless, the relationship between magnitudes of \(\eta_a\) and \(\eta^*\) can be dependent on the strain amplitude used.\(^{(38)}\)

3 STIMULI FOR EVALUATION OF VISCOSITY

To describe the mouthfeel of beverages, 136 terms were generated from 5350 responses.\(^{(39)}\) Of the 136 terms, 30.7% were viscosity-related terms. In addition, it was suggested that the term “mouthfeel” was better than “viscosity” that was applicable to liquid foods, whereas the former has the same meaning as “texture”. Wood\(^{(40)}\) suggested that the stimulus associated with oral assessment was the apparent viscosity determined at 50 s\(^{-1}\). Shama and Sherman\(^{(41)}\) made an important contribution in identifying the stimuli associated with sensory assessment of foods by oral methods. They showed that the stimulus depends on whether one is dealing with a low-viscosity or a high-viscosity food.

As illustrated in Figure 9 for low-viscosity foods, the stimulus is the shear rate developed at an almost constant shear stress of 10 Pa. In contrast, for high-viscosity foods, the stimulus is the shear stress developed at an approximately constant shear rate of 10 s\(^{-1}\). Other studies on the stimuli associated with nonoral assessment of viscosity and perceived thickness of liquid foods have been reviewed.\(^{(2)}\)

4 VELOCITY PROFILES IN TUBE FLOW

Equations describing velocity profiles can be used, among other applications, to study the effect of different rheological models on the distribution of velocities and to understand the concept of residence time distribution across the cross-section of a pipe or a channel. The velocity profile of a fluid flowing in a tube can be derived from Equation (41),

\[
v_z = \frac{r_o}{r} \left( \frac{dv_z}{dr} \right) dr
\]

where \(v_z\) is the velocity in the axial direction, \(r\) is the radial coordinate, and \(r_o\) is the radius of the tube (Figure 10). A simple force balance for tube flow yields Equation (42),

\[
\sigma_{rz} = \sigma_w r o = \frac{r dp}{2 dz}
\]

where \(\sigma_{rz}\) is the shear stress at any radius \(r\), \(\sigma_w\) is the magnitude of the shear stress at the wall (\(r = r_o\)), \(p\) is the pressure, and \(z\) is the axial coordinate. Utilizing Equations (36) and (37), and noting that in the rheological equations \(\sigma = \sigma_{rz}\) and \(\dot{\gamma} = (dv_z/dr)\), one can derive equations describing the velocity profiles for laminar flow in a tube.

The power law model (Equation 4) has been used extensively in handling applications. The relationship between the maximum velocity (\(v_{zm}\)) and the average velocity (\(\bar{v}\)) for the design of the length of a holding tube of a pasteurizing system is of special interest (Equation 43):

\[
\frac{v_{zm}}{\bar{v}} = \frac{3n + 1}{n + 1}
\]

Figure 9 The curved lines represent borders of the stimuli associated with sensory assessment of foods by oral methods. Constant-viscosity lines are also shown (1 P = 0.1 Pa s). (Reproduced by permission of Food and Nutrition Press, Inc., from Sharma and Sherman.\(^{(41)}\))

Figure 10 Diagram of the coordinate system for velocity profiles in tube flow.
For Newtonian and pseudoplastic fluids in laminar flow, one can deduce from Equation (38), the popular relationship that maximum velocity, at most, is equal to twice the average velocity. In contrast, in the case of shear thickening (dilatant) fluids, the maximum velocity would be more than twice the average velocity.

The volumetric flow rate \( Q \) is given by Equation (44)

\[
Q = \frac{r_o^5}{2\pi} v_z \, dr = \pi \frac{r_o}{r} v_z(r) \, dr^2
\]

Integrating by parts the second part of Equation (39), and using the boundary condition \( v = 0 \) at \( r = r_o \), one can obtain the general equation for the volumetric flow of a fluid in a tube (Equation 45):

\[
Q = \left( \frac{\pi r_o^5}{\sigma_w^0} \right) \left( \frac{\sigma_w}{\sigma_w^0} \right)^{\frac{m}{n}} \left( \frac{d^2 v_z}{dr^2} \right) \, dr
\]

</tbody>
</table>

\( a \) The average velocity can be obtained by dividing the equation for volumetric flow rate by the area of cross-section of the pipe.

\( b \) Maximum velocity occurs at the centerline, \( r = 0 \).

\( c \) Velocity profiles are valid for \( r_o \leq r \leq R \), where the radius of plug \( r_o = (2\eta_0 L/\Delta p) \); the maximum velocity occurs when \( 0 \leq r \leq r_o \), and is obtained by substituting \( r_o \) for \( r \).

Substituting for the shear rate appropriate expressions from different rheological models, one can derive equations relating \( Q \) and pressure drop \( \Delta p \). Table 2 contains expressions for the velocity profiles and the volumetric flow rates of the three rheological models: the power law, Herschel–Bulkley, and the Bingham plastic models.

In the case of fluids obeying the power-law model, the pressure drop per unit length \( \Delta p/L \) is related to \( Q \) and \( r_o \) by the relationship:

\[
\frac{\Delta p}{L} \propto \frac{Q^n}{r_o^{3n+1}}
\]

From Equation (46) it can be seen that for Newtonian foods \( (n = 1) \) the pressure gradient is proportional to \( (r_o)^{-4} \). Therefore, a small increase in the radius of the tube will result in a major reduction in the magnitude of the pressure gradient. In contrast, for a highly pseudoplastic fluid \( (e.g. n = 0.2) \), increasing the pipe radius does not have such a profound effect on the pressure gradient.

## 5 ENERGY REQUIREMENTS FOR PUMPING

### 5.1 Mechanical Energy Balance Equation

The energy required to pump a liquid food through a pipeline can be calculated from the mechanical energy balance (MEB) equation. The MEB equation can be used to analyze pipe flow systems. For the steady-state flow of an incompressible fluid, the MEB can be written as Equation (47):

\[
gZ_1 + \frac{P_1}{P} + \frac{v_1^2}{2g} - W = gZ_2 + \frac{P_2}{P} + \frac{v_2^2}{2g} + E_t
\]

where \( g \) is the acceleration due to gravity, \( Z \) is the height above a reference point, \( P \) is the pressure, \( v \) is the fluid velocity, \( W \) is the work output per unit mass, \( E_t \) is the energy loss per unit mass, \( \alpha \) is the kinetic energy correction factor, and the subscripts 1 and 2 refer to two points in the pipe system. In order to accurately estimate the energy required for pumping of a food in a specific piping and equipment system, the term \( (\Delta W) \) \( (1 \text{ kg}^{-1}) \) has to be estimated from Equation (47) after the other terms have been evaluated.(24)

The velocities at the entrance and exit of the system can be calculated from the volumetric flow rate of the food, and the respective diameters of the tanks or pipes. The energy loss term \( E_t \) consists of losses due to friction in pipe and that due to friction in valves and fittings:

\[
E_t = \frac{2f v_z L}{D} + \sum_{1}^{b} \frac{k_i v_i^2}{2}
\]
where \( f \) is the pipe friction factor, \( v_z \) is the velocity, \( L \) is the length of straight pipe of diameter \( D \), \( k_f \) is the friction coefficient for a fitting, and \( b \) is the number of valves or fittings. It is emphasized that \( k_f \) is unique to a particular fitting and that different values of \( u, k_f, \) and \( f \) may be required when the system contains pipes of different diameters. Further, losses due to special equipment, such as heat exchangers, must be added to \( E_t \).\(^{42} \)

### 5.2 Friction Losses in Pipes

Because many fluid foods are non-Newtonian in nature, estimation of friction losses (pressure drop) for these fluids in straight pipes is of interest. One can estimate the friction losses in straight pipes and tubes can be estimated from the magnitude of the fanning friction factor \( f \) (Equation 49):

\[
\frac{\Delta P_i}{\rho} = \frac{2fL v_z^2}{D}
\]  

(49)

For fluids that can be described by the power law (Equation 4), the generalized Reynolds number (GRe) is calculated from Equation (50):

\[
\text{GRe} = \frac{D^n v_z^{2-n} \rho}{8(n-1)K} \left( \frac{4n}{3n+1} \right)^n
\]

(50)

where \( D \) is the pipe diameter, \( v_z \) is the average velocity, \( \rho \) is the density, and \( K \) and \( n \) are the power law parameters of the food. When \( n = 1 \), Equation (50) reduces to the Reynolds number for Newtonian foods:

\[
\text{Re} = \frac{D v_z \rho}{\eta}
\]

(51)

In laminar tube flow, the fanning friction factor can be calculated from Equation (52):

\[
f = \frac{16}{\text{GRe}}
\]

(52)

This relationship can also be used for Newtonian fluids in laminar flow with the Reynolds number being used in place of GRe. In fact, the Newtonian \( f \) versus Re relationship was established much earlier than extension to non-Newtonian fluids. Once the magnitude of the friction factor is known, the pressure drop in a pipe can be estimated from Equation (49).

#### 5.2.1 Friction Loss Coefficients for Fittings

Steffe et al.\(^{43} \) determined magnitudes of the coefficient of a fully open plug valve, a tee with flow from line to branch, and a 90° short elbow as a function of GRe using apple sauce as the test fluid. They found that, as for Newtonian fluids, \( k_f \) increases with decreasing values of GRe. The regression equations for the three fittings are given by Equations (53–55):

- three-way plug valve: 
  \[ k_f = 30.3 \text{GRe}^{-0.492} \]  
  (53)

- tee: 
  \[ k_f = 29.4 \text{GRe}^{-0.504} \]  
  (54)

- elbow: 
  \[ k_f = 191.0 \text{GRe}^{-0.896} \]  
  (55)

In many instances, the practice is to employ values determined for Newtonian fluids, such as those in the Chemical Engineers’ Handbook.\(^{44} \)

### LIST OF SYMBOLS

- \( c \) polymer or solute concentration (w w\(^{-1} \))
- \( c^* \) coil overlap concentration (w w\(^{-1} \))
- \( cQ \) starch granule mass fraction
- \( D \) starch granule and pipe diameter
- \( E_a \) activation energy of flow (J mol\(^{-1} \))
- \( E_f \) energy loss per unit mass (J kg\(^{-1} \))
- \( E_g \) activation energy of gelatinization (J mol\(^{-1} \))
- \( E_i \) elastic modulus (Pa)
- \( E_{ak}, E_{aj} \) activation energy for viscous flow
- \( f \) Fanning friction factor, dimensionless
- \( G' \) storage modulus (Pa)
- \( G'' \) loss modulus (Pa)
- \( G^* = (G')^2 + (G'')^2 \) complex modulus (Pa)
- \( K, K_{H1} \) consistency index (Pa s\(^n\))
- \( k_f \) is friction coefficient of a fitting
- \( L \) length of tube/pipe (m)
- \( n, n_{H1} \) flow behavior index, dimensionless
- \( p \) pressure (Pa)
- \( r_i \) radius of inner cylinder (m)
- \( r_o \) radius of outer cylinder; particle radius (m)
- \( R \) gas constant (8.314 J mol\(^{-1} \) K\(^{-1} \))
- \( T \) temperature of fluid (°C, K)
- \( v_z \) velocity (m s\(^{-1} \))
- \( W \) work per unit mass (J kg\(^{-1} \))
- \( Z_1 \) and \( Z_2 \) heights above a reference point (m)
Greek Letters

\( \delta \)  
phase angle (rad)

\( \gamma(t) \)  
oscillatory strain or deformation

\( \dot{\gamma} \)  
shear rate (s\(^{-1}\))

\( \gamma_0 \)  
strain amplitude

\( \eta_0 \)  
apparent viscosity (Pa s)

\( \eta_{Ca} = (K_c)^2 \)  
Casson viscosity (Pa s)

\( \eta_0 \)  
zero shear viscosity (Pa s)

\( \eta^* = \left( \frac{G^*}{\omega} \right) \)  
complex viscosity (Pa s)

\( \eta_\infty \)  
infinite shear viscosity (Pa s)

\( \phi \)  
volume fraction, \( \phi = cQ \) for starch dispersions

\( \phi_m \)  
maximum volume fraction

\( \rho \)  
density (kg m\(^{-3}\))

\( \sigma \)  
shear stress (Pa)

\( \sigma_{0c} = (K_{0c})^2 \)  
Casson yield stress (Pa)

Dimensionless Numbers

\( \text{Re} \)  
Reynolds number, \( \frac{D v_2 \rho}{\eta} \)

\( \text{GRe} \)  
pipe flow generalized Reynolds number \( \text{GRe} = \frac{D^n v^2 \rho}{8^\frac{n}{2g}} \left( \frac{4n}{3n + 1} \right) \)

Significant advances have been made in vitamin assay methodology since the 1970s. Older, established methods include chemical methods such as the thiochrome method for thiamin and the various chemical procedures available for ascorbic acid (AA). Such methods, together with microbiological methods still comprise the bulk of accepted methods of vitamin analysis available in methodology sources, including *Official Methods of Analysis*, 16th edition [Association of Official Analytical Chemists (now known as AOAC International) (AOAC) International, Arlington, VA, 1995]. Most advances in vitamin quantification have come through use of HPLC. At present, HPLC can be used for quantification of each of the vitamins depending upon the matrix and concentration of the vitamin. For each of the water-soluble vitamins except AA, microbiological assay is routinely used for food analysis. Since the field is so large, we have attempted in this article to present an overview of useful approaches to vitamin assay. Realizing the scope of the subject, our concentration is on HPLC assays. Reference is made to several recent texts for readers needing more complete information.

2 CHEMISTRY

2.1 Vitamin A and Carotenoids

The structure of all-trans-retinol (vitamin A) is given in Figure 1. Vitamin A refers to all isoprenoid compounds from animal products that possess the biological activity of all-trans-retinol which could prevent night blindness and xerophthalmia. The parent vitamin A compound, retinol, contains a \( \beta \)-ionone (cyclohexenyl) ring attached at the C-6 position to a side chain composed of two isoprene units. The four double bonds in the polyene side chain give rise to cis–trans \((Z–E)\) isomerism. Retinoids include all substances with vitamin A activity, some of which differ structurally from all-trans-retinol. Retinyl acetate and retinyl palmitate are used commercially in synthetic form by the pharmaceutical and food industry. Esterification greatly stabilizes the vitamin toward oxidation.

Vitamin A has strong ultraviolet (UV) absorption properties owing to the conjugated double bond system. Absorption maxima vary depending on the solvent and the presence of cis-isomers (\(Z\)-). Isomerization to the cis form lowers the absorption maximum and molar absorptivity \((A_{\text{1cm}})\) values relative to all-trans-retinol.\(^1\) Retinol and retinyl esters exhibit strong native fluorescence with excitation and emission maxima at wavelengths of 325–330 and 470–490 nm, respectively.\(^2\)
Physical properties of all-trans-retinol, all-trans-retinyl palmitate and all-trans-retinal are given in Table 1.

2.1.2 Carotenoids

Carotenoids are classified chemically as carotenes, which are hydrocarbons and xanthophylls. The structures are formed by the head-to-tail linkages of isoprene units to provide a C₄₀ skeleton. Lycopene (Figure 1) shows the acyclic hydrocarbon backbone chain. Structural modifications of lycopene lead to the diverse nature of the carotenoids present in the plant kingdom. The nutritionally most important carotenoid, β-carotene, is composed of two molecules of retinol joined tail to tail (Figure 1); thus, the compound possesses maximum provitamin A activity. Addition of oxygenated functions to the molecule yields the xanthophylls. These oxygen-containing groups include hydroxyl, carbonyl, carboxylic acid, ester, epoxide, glycoside and ether.

Physical properties of β-carotene are given in Table 1.

2.2 Vitamin D

Vitamin D is the inclusive term for steroids that are antirachitic. There are only two D vitamins of significance nutritionally and biologically, vitamin D₂ and D₃, which are also known as ergocalciferol and cholecalciferol, respectively. The structures of vitamin D₂ and D₃ are given in Figure 1. Vitamin D₂ and vitamin D₃ differ structurally by only a double bond and an additional methyl group in the side chain of vitamin D₂. All vitamin D forms show a characteristic broad UV spectrum with a maximum absorption near 264 nm and a minimum near 228 nm. Vitamin D does not fluoresce.

Physical properties of vitamin D are given in Table 1.

2.3 Vitamin E

Vitamin E includes Ts and T₃s (Figure 2) that possess the biological activity of α-T. They occur in nature as a group of substances including eight chemically similar compounds which are derivatives of 6-chromanol. The Ts have a phytol side chain and the T₃s have a similar structure with double bonds at the 3’, 7’ and 11’ positions of the side chain. The four homologs of Ts and T₃s differ in the number and location of the methyl groups on the chroman ring. Because of the presence of three asymmetric carbon atoms at position 2 of the chroman ring and at the 4’ and 8’ carbons of the side chain, the Ts...

<sup>a</sup> Table adapted from Eitenmiller and Landen<sup>5</sup>.

<sup>b</sup> In hexane (Hex); bold values in 2-propanol (IPA).

T<sub>3</sub>, tocotrienol; T<sub>1</sub>, tocopherol; PE, petroleum ether; MK-4, menaquinone-4.
can exist in eight diastereomeric forms. T3s with double bonds in the side chain can form cis and trans isomers.

Physical properties of vitamin E homologs are given in Table 1.

### 2.4 Vitamin K

Vitamin K is used as a generic descriptor for 2-methyl-1,4-naphthoquinone and all its derivatives providing the antihemorrhagic activity of vitamin K1, phylloquinone.\(^6\) Figure 2 shows the structures of vitamin K1, vitamin K2 and vitamin K3. Vitamin K3, known as menadione, is the synthetic and simplest form of vitamin K. Vitamin K1 is synthesized by green plants in the chloroplasts at position 3 of the 2-methyl-1,4-naphthoquinone ring with five-carbon isoprenoid units produces the vitamin K series found in nature, K1\(^{19}\), the most common being phylloquinone. Vitamin K2 refers to a family of structural analogs called the menaquinone-\(n\) series (MK-\(n\)) (Figure 2), the predominant members of which have side chains composed of 6–10 unsaturated isoprene units.\(^9\)

Physical properties of phylloquinone, MK-4 and menadione are given in Table 1.

### 2.5 Vitamin C

Vitamin C refers to compounds exhibiting full or partial biological activity of L-AA that prevent and cure scurvy. These include esters of AA such as ascorbyl palmitate, 100% relative activity, synthetic forms (6-deoxy-L-AA, 33% relative activity) and the primary oxidized form of L-AA, dehydroascorbic acid (DHAA), with 80% relative activity.\(^{10}\) The structures of L-AA and related compounds are given in Figure 3. L-AA and DHAA are the primary dietary sources of vitamin C. Since animals efficiently reduce DHAA to L-AA, both forms must be measured to quantitate accurately “total” vitamin C activity of food or other biological samples.\(^{11}\) L-AA is a widely used food additive with many functional roles, many of which are based upon its oxidation-reduction properties.

The UV absorption of L-AA is strongly pH dependent: at pH 2 the absorption maximum is at 245 nm and at pH 6.4 it is at 265 nm.\(^{12}\) L-AA does not fluoresce, but its derivatization with o-phenylenediamine (OPD) gives a highly fluorescent product which is used advantageously in chemical and HPLC methods. Physical properties of L-AA are given in Table 2.

### 2.6 Thiamin (Vitamin B\(1\))

Thiamin is characterized by a pyrimidine linked by a methylene bridge to a substituted thiazole (Figure 3). The naturally occurring thiamin exists as thiamin pyrophosphate (TPP) (Figure 3), whereas thiamin hydrochloride and thiamin mononitrate are the commercially available forms used in pharmaceuticals and for food fortification. Physical properties of the thiamin salts are given in Table 2. The most distinguishing difference between the hydrochloride salt and the mononitrate is water solubility. The hydrochloride is soluble in water (1 g mL\(^{-1}\)) and the mononitrate is only slightly water-soluble (0.027 g mL\(^{-1}\)).\(^5\)

The absorption spectrum of thiamin hydrochloride is pH dependent. At pH 2.9, a single maximum is present at 246 nm. At pH levels above 5 but below neutrality, two absorption maxima exist at 234 and 264 nm, representing the pyrimidine and thiazole rings, respectively.\(^{13}\)

### 2.7 Riboflavin (Vitamin B\(2\))

Riboflavin, 7,8-dimethyl-10-(1’-D-ribityl)isoalloxazine, is the generic term for the group of compounds that exhibit the biological activity of riboflavin (Figure 3). Phosphorylation of the 5’-position of the ribityl side chain of the pyrimidine ring gives an increased hydrophilicity, important for the biological activity of riboflavin.\(^{14}\)
chain yields flavin mononucleotide (FMN) and addition of 5′-adenosyl monophosphate moiety yields FAD. The carbon–nitrogen bond linking the ribityl side chain to the isalloxazine withstands hydrolysis, whereas FMN and FAD are easily converted to riboflavin below pH 5.0. Therefore, analytical procedures often incorporate acid hydrolysis as the first step, with subsequent quantitation of total riboflavin. In contrast, acid hydrolysis must be avoided in the quantitation of the coenzyme forms. Riboflavin is a yellow-green, light-sensitive compound and is widely distributed in animal and plant cells.

The characteristic spectral properties of riboflavin, FMN and FAD provide the basis for analytical methods for their determination. Most chemical and HPLC methods capitalize on the strong native fluorescence of the flavins with excitation wavelength from 440 to 500 nm and emission wavelength from 520 to 530 nm. In aqueous solutions, riboflavin shows absorption maxima of 223, 266, 373 and 445 nm. Physical properties of riboflavin, FMN and FAD are given in Table 2.

2.8 Niacin

Niacin is the generic descriptor for nicotinic acid and nicotinamide, which have equal biological activities. The coenzyme forms of niacin are nicotinamide adenine dinucleotide (NAD) and nicotinamide adenine dinucleotide phosphate (NADP). Nicotinic acid has been designated as pyridine-3-carboxylic acid and nicotinamide is known as pyridine-3-carboxamide (Figure 4). Both compounds are white, needle-shaped crystals. Nicotinamide is more water-soluble (100 g per 100 mL) than nicotinic acid (1.67 g per 100 mL).

Nicotinic acid and nicotinamide show similar absorption properties with an absorption maximum near 260 nm. The absorption intensity is strongly affected by pH. The absorptivity is higher in acidic than in alkaline solution. Niacin does not fluoresce; however, the coenzymes fluoresce at 470 nm when excited at either 260 or 340 nm.

2.9 Vitamin B₆

Vitamin B₆ is a generic term for the group of 2-methyl-3-hydroxy-5-hydroxymethylpyridine compounds that possess the biological activity of PN in rats. There are six known B₆ vitamers in nature: PN or pyridoxine, pyridoxal (PL), PM, with alcohol, aldehyde and amine groups in the 4-position, respectively. The phosphorylation at the 5′-hydroxymethyl group of PN, PL and PM yield pyridoxine-5′-phosphate (PNP), pyridoxal-5′-phosphate (PLP) and pyridoxamine-5′-phosphate (PMP), respectively. PN, PL and PM are metabolically interconvertible and considered to be biologically active equivalents. The structure of PN (vitamin B₆) is given in Figure 4.

The UV absorption spectra of PL, PN, PM and their 5′-phosphate esters are similar (in 0.1 M HCl) and the absorption maxima are at about 290 nm. At pH 7.0, PN, PM, PNP and PMP have absorption maxima at 253 and 325 nm, whereas the other vitamers absorb maximally at 390 nm. Physical properties of vitamin B₆ are given in Table 2.

2.10 Folate

Folate is the general term inclusive of folic acid (pteroyl glutamate) and poly-γ-glutamyl conjugates that exhibit the biological activity of folic acid. The structure of folic acid is given in Figure 4. Folate refers to the large group of heterocyclic compounds based on the pteroic acid structure conjugated with one or more L-glutamates linked through the γ-carboxyl group of the amino acid. Folic acid is not found in nature; rather, it is in its reduced form, either dihydrofolate (H₂ folate) or tetrahydrofolate (H₄ folate). Folic acid is yellow and slightly soluble in water in the acid form but fairly soluble in the salt form.

*Source: references 14, 13, 19, 21, 31–33*)

*Table adapted from Eitenmiller and Landen. 5*

*Values in bold are calculated from corresponding \( \varepsilon \) values.

*Values in parentheses are pH range.

FAD, flavin adenine dinucleotide; PN, pyridoxine; PM, pyridoxamine; TPP, thiamin pyrophosphate.
Pounds have been reported by Uyeda and Rabinowitz.

Properties of naturally occurring folate and related compounds are possible. D-(2,4-dihydroxy-3,3-dimethyl-1-oxobutyl)-β-alanine. The trivial name is D-(+)-α,γ-dihydroxy-β,β-dimethylbutyl-β-alanine. The molecule is optically active but only the D-(+)-enantiomers are biologically active and present in nature. Synthetic pantothentic acid is a racemophore. The carbonyl group absorbs weakly below 210 nm. The physical properties of pantothentic acid are given in Table 2.

2.11 Vitamin B12

Vitamin B12 is the collective name for cobalt-containing corrinoids with the biological activity of cyanocobalamin. Cyanocobalamin is the permissible or trivial name for vitamin B12. Nutritional references to vitamin B12 usually refer to all cobalamins biologically active in humans. Aqueous solutions of cyanocobalamin have absorption maxima at 278, 361 and 551 nm. Physical properties of cyanocobalamin are given in Table 2.

2.12 Biotin

Biotin is cis-hexahydro-2-oxo-1H-thieno[3,4-d]imidazole-4-pentanoic acid. The molecule contains three asymmetric carbon atoms and therefore eight stereoisomers are possible. D-(+)-Biotin is the only biologically active form and other isomers are not found in nature. The structure of biotin is shown in Figure 4. In nature, biotin occurs free or bound through ε-amino linkages with lysine as biocytin or to carrier proteins and peptides. Physical properties of biotin are given in Table 2. Biotin shows weak absorbance at 200–220 nm with an absorption maximum at 204 nm from the carbonyl group. HPLC methods are only useful for the assay of highly concentrated pharmaceuticals or vitamin premixes unless the UV absorbance or fluorescence is enhanced through derivatization.

Figure 4 Selected structures of niacin, vitamin B6, folate, biotin and pantothenic acid.

2.13 Pantothenic Acid

Pantothenic acid (Figure 4) is systematically named D-(+)-N-(2,4-dihydroxy-3,3-dimethyl-1-oxobutyl)-β-alanine. The trivial name is D-(+)-α,γ-dihydroxy-β,β-dimethylbutyl-β-alanine. The molecule is optically active but only the D-(+)-enantiomers are biologically active and present in nature. Synthetic pantothentic acid is a racemophore. The carbonyl group absorbs weakly below 210 nm. The physical properties of pantothentic acid are given in Table 2.

3 ANALYSIS OF WATER-SOLUBLE VITAMINS

3.1 Microbiological Methods

Microbiological assays are available for each water-soluble vitamin except AA. These assays were concurrently developed with, or shortly after, development of bioassays for the different vitamins earlier in the twentieth century. Therefore, the method development activities and the availability of analytical procedures that provide similar responses to longer duration bioassays played a historically significant role in understanding not only microbial metabolism but also human and animal metabolism. Interestingly, except in a few cases, methodology developed during the 1940s has remained essentially unchanged. Microbiological assay of the watersoluble vitamins continues to play a major role in current vitamin analysis programs. Although HPLC techniques are available, microbiological techniques have not been replaced by the chromatographic assays. Microbiological assays offer specificity and sensitivity in a cost-effective manner often not obtainable with HPLC methods.

Microbiological vitamin assays utilize dose–response curves of microorganisms that possess a highly specific requirement for the vitamin. Such requirements need to be absolute in that the nutritional requirement for the vitamin can not be altered by other naturally occurring compounds. When this requirement is met by the microorganism, a basal medium can be formulated to provide all of the growth requirements of the microorganism, a standard or an extract of the material to be quantified. The fluorescence intensity increases as the acidity of the solvent increases. Physical properties of folates are given in Table 2. Microbiological assays played a historically significant role in understanding the metabolic activities and the availability of analytical procedures that provide similar responses to longer duration bioassays played a historically significant role in understanding not only microbial metabolism but also human and animal metabolism. Interestingly, except in a few cases, methodology developed during the 1940s has remained essentially unchanged. Microbiological assay of the water-soluble vitamins continues to play a major role in current vitamin analysis programs. Although HPLC techniques are available, microbiological techniques have not been replaced by the chromatographic assays. Microbiological assays offer specificity and sensitivity in a cost-effective manner often not obtainable with HPLC methods.

Microbiological vitamin assays utilize dose–response curves of microorganisms that possess a highly specific requirement for the vitamin. Such requirements need to be absolute in that the nutritional requirement for the vitamin can not be altered by other naturally occurring compounds. When this requirement is met by the microorganism, a basal medium can be formulated to provide all of the growth requirements of the organism except for the vitamin being assayed. When a standard or an extract of the material to be quantified is added to the clear growth medium, the microorganism
reproduces in proportion to the amount of added vitamin. Over a defined concentration range, the response will be directly proportional to the amount of vitamin present. Within this range, sample and standard solutions can be compared accurately.\(^{(30)}\) Growth is measured by turbidity, production of metabolite (acid), gravimetrically or by respiration.

Requirements of bacteria, yeast, molds, and protozoans have been well defined. Microorganisms chosen for water-soluble vitamin assays must not be able to synthesize vitamin, utilize metabolites not active for humans or animals or utilize structurally related compounds. The microorganism, therefore, must possess the following characteristics: (1) specifically, require vitamin forms that are biologically active in higher animals; (2) be genetically stable; (3) possess a rapid growth cycle; (4) provide a growth response that is not easily modified by other substances that are present in the extract (stimulators or inhibitors); and (5) be nonpathogenic.\(^{(30)}\)

Eitenmiller\(^{(30)}\) summarized the advantages and disadvantages of microbiological assay as follows. Advantages: (1) sensitive; (2) capable of assaying naturally occurring levels from complex matrices (food samples); and (3) minimal laboratory requirements of space, materials and instrumentation. Disadvantages: (1) labor intensive; (2) poor precision; (3) difficult to streamline or automate, with limited sample output; (4) varying responses of the assay organism to different vitamin forms (bound forms or multiple chemical forms); (5) simultaneous vitamin assay not possible; (6) drift problems; and (7) provides little information on bioavailability.

Compared with bioassays using animals, microbiological assay requires less space, labor, material and time. Start-up costs can be minimal.

Because of extensive use worldwide, the assay techniques have been reviewed extensively and readers requiring in-depth knowledge are referred to the literature.\(^{(5,9,11,13,16,34)}\)

As an overall reference to currently accepted procedures, AOAC International\(^{(34)}\) presents detailed procedural guides for the analysis of many different food matrices. Since it is beyond the scope of this brief article to cover assays for each water-soluble vitamin, we have provided an overview in Table 3.

3.2 Chromatographic Methods

HPLC is the most commonly used chromatographic method to assay water-soluble vitamins. HPLC can provide selectivity and accuracy with fast results and the ability to assay different forms of the vitamin in biological matrices. HPLC techniques have been widely used for the simultaneous determination of fat-soluble vitamins in food; however, their application to water-soluble vitamin analysis is limited owing to the availability of sufficiently sensitive and specific detection systems that are capable of quantifying several vitamins from a complex mixture of compounds. Examples of selected HPLC methods for water-soluble vitamins are given in Table 4; Ball and Eitenmiller and Landen provide in-depth reviews on HPLC procedures for water-soluble vitamin analysis.

Only reversed-phase high-performance liquid chromatography (RP-HPLC) is used in water-soluble analysis owing to the chemical properties of this group. Columns used vary depending on the analytes; they include ion-exchange columns for vitamin C and niacin, PLRP-S for riboflavin and vitamin C, and C18 columns for most analytes. The mobile phase consists of methanol or acetonitrile together with water, acetic acid or buffers. The extraction procedures usually involve acid hydrolysis for vitamin C, thiamin, riboflavin, niacin and vitamin B6, and enzyme hydrolysis for thiamin, riboflavin, niacin, vitamin B6 and folate. UV, EC and fluorescence detectors have often been used in the methods. Pre- or postderivatization is used for those analytes that lack native fluorescence.

Some multianalyte methods are available for the determination of riboflavin and thiamin and, occasionally, other water-soluble vitamins. A simultaneous determination of thiamin and riboflavin in selected foods was described by Sims and Shoemaker. After autoclave extraction, samples are derivatized to form thiochrome (a highly fluorescent oxidation product of thiamin). Riboflavin has strong native fluorescence. The interferences were removed on a C18 cartridge. Analytes were separated on a reversed-phase system with a nonaqueous mobile phase. Detection limits were 0.05 ng and relative standard deviations were <2% for both analytes.

Albalá-Hurtado et al. reported a rapid HPLC method for the determination of nicotinamide, thiamin, riboflavin, PN, PL, PM, cyanocobalamine and folic acid in liquid and powdered infant milk. Sample preparation involved acidification to precipitate proteins, centrifugation, then filtration. Ion-pair chromatography with a reversed-phase C18 column was used for analysis of the six vitamins. Methanol–water (15:85) containing 5 mM octanesulfonic acid with 0.5% triethylamine at pH 3.6 was used as the mobile phase. The method is simple and reliable.

4 ANALYSIS OF FAT-SOLUBLE VITAMINS

4.1 Chromatographic Methods

Chromatographic methods are the most versatile and useful methods for the determination of the fat-soluble vitamins. These methods include column chromatography, paper chromatography, thin-layer chromatography (TLC), gas chromatography (GC) and HPLC.

Paper chromatography has been used by several workers for the determination of Ts. However, paper chromatography is tedious, time-consuming and inaccurate for the quantification of individual Ts. TLC, compared with paper chromatography, has several advantages, which include a shorter development time, superior separation of the individual Ts, larger loading capacity and better quantitative elution of compounds from the absorbent. TLC has traditionally been a method of choice for the analysis of lipophilic compounds and for confirming the purity of concentrated solutions of retinoids and carotenoids, where impurities that do not absorb markedly at the wavelength of detection or that elute slowly from the HPLC column might not be detected. For quantitative analysis, HPLC or GC have surpassed TLC, as quantitative TLC assays lack precision, are labor intensive and are difficult to automate. Moreover, the risk of oxidative losses by exposing Ts on large surface areas to light and air is enhanced. However, TLC, has value as a straightforward and inexpensive qualitative or semiquantitative assay method.

GC is a useful technique for the simultaneous separation and quantitative detection of free Ts, T esters and their derivatives. However, it has limited value in retinoid analysis owing to the instability of conjugated unsaturated compounds. With respect to vitamin E analysis, GC is fairly sensitive and microgram quantities of different Ts can be readily detected. Sample preparation for GC analysis of vitamin E is more critical than with other chromatographic techniques. Interferences of lipids present in the unsaponifiable fraction of biological materials are more likely to occur. As a result, sample pretreatment prior to GC often becomes tedious and time-consuming.

The two major, distinct methods of HPLC separation are referred to as normal-phase (adsorption) chromatography and reversed-phase (partition) chromatography. In normal-phase chromatography, the sample is preferentially adsorbed on a polar stationary phase, usually silica (sometimes alumina), and displaced from its adsorption sites by mobile phase, typically Hex containing small amounts of polar modifiers. Hence less polar compounds elute before more polar compounds. RPHPLC
is characterized by partitioning of the sample between a hydrophobic stationary phase (typically C2, C8, C18 or phenyl chains covalently bonded to silica particles) and a more polar mobile phase, typically methanol or acetonitrile with small amounts of water added. In contrast to adsorption chromatography, polar components are eluted before less polar components in RPHPLC. RPHPLC has many advantages over the normal-phase mode, such as (1) less sensitivity to changes in retention time due to the presence of water; (2) more easily cleaned of contaminants; (3) more stable to small changes in mobile phase composition; (4) more quickly equilibrated to mobile phase composition changes, permitting use of gradients; and (5) capable of resolving compounds with a wide range of polarities. (1,102,104–106) Adsorption HPLC, however, is capable of resolving compounds (e.g. geometric isomers of retinoids and the β- and γ-positional isomers of vitamin E) that are difficult or impossible to separate by RPHPLC. HPLC for the determination of fat-soluble vitamins can be utilized in both normal-phase and reversed-phase modes. However, β- and γ-isomers of the Ts and T3s cannot be separated by RPHPLC. (107–112) Moreover, the nonpolar column does not tolerate heavy loads of triglycerides or other nonpolar compounds. (112,113) Normal-phase columns can tolerate lipid up to 2 mg per injection. (113)

Efficient extraction of vitamins from the sample matrix before HPLC analysis is as important as the determinative chromatography. Extraction can be very time-consuming. The extraction methods used for fat-soluble vitamins include alkaline hydrolysis (saponification), enzymatic hydrolysis, direct solvent extraction, Soxhlet extraction and supercritical fluid extraction (SFE) of the total lipid component.

Saponification is the most widely used and generally accepted method for the determination of vitamins A, D and E and carotenoids. It is conventionally carried out by refluxing an appropriate amount of suitably prepared sample with ethanolic KOH solution, in the presence of an antioxidant, such as pyrogallol, (113–115) or AA, (116–118) with heat treatment (115,117,119–121) or without heat treatment. (122,123) The unsaponifiable matter containing the fat-soluble vitamins, sterols, carotenoids etc. is extracted with Hex (116,123) or a mixture of ethyl acetate and Hex (124,125) or PE (121), leaving the fatty acid salts and other water-soluble components behind. The liberation of the unstable retinol from the relatively stable esters during saponification demands protective measures against light and oxygen during the analysis.

Several factors affect the efficiency of the extraction. In 1987, Ueda and Igarashi (126) reported that the ethanol concentration in the extraction medium must be kept below 30% for the quantitative extraction of Ts and increasing levels of co-existing fat decreased the extraction recovery of Ts, except α-T. Hewawitharana and van Brakel (117) found that the use of 3% (m/v) AA in the saponification mixture along with the addition of butylated hydroxytoluene (BHT) to the extracting solution gave higher recoveries of retinol, α-T and β-carotene compared with the use of ethanolic pyrogallol or 0.5% (m/v) ethanolic AA alone. Saponification could reduce the recovery of all Ts and in particular, δ-T (114,126–129) and α-T. (128) The reduction in recovery was dependent on the concentration of KOH, (127) the temperature of saponification [room temperature (15, 20 °C) vs 70 °C] (114,126,128) and triacylglycerol content. (126) Saponification is a cheap and easy method, but time-consuming, and the process often facilitates the isomerization of α- and β-carotene and destruction of α-T. (130) Owing to the instability of vitamin K under alkaline conditions, saponification cannot be used for extraction.

Enzymatic hydrolysis using lipase has been employed as an effective alternative to saponification to reduce the risk of vitamin degradation. For the simultaneous determination of vitamins A, D, E and K in fortified milk- and soy-based infant formulas and dairy products, (131) an amount of sample containing approximately 3.5–4.0 g of fat was digested for 1 h with lipase at 37 °C and pH 7.7. The hydrolyzate was made alkaline in order to precipitate the fatty acids as soaps. The solution was then diluted with ethanol and extracted with pentane. A final water wash yielded an organic phase containing, primarily, the fat-soluble vitamins and cholesterol. This treatment effectively hydrolyzed the glycerides, but only partially converted retinyl palmitate and α-tocopheryl acetate to their alcohol forms. (135) Lietz and Henry (130) used nonspecific Candida cylindracea lipase to achieve complete hydrolysis of red palm oil after 4 h with no significant loss of carotenoids and Ts.

Soxhlet extraction is often the simplest and most efficient method for vitamin E extraction if the sample is dry. (5) Häkansson et al. (109) used Soxhlet extraction for the determination of vitamin E in wheat products. The sample (5–15 g) was weighed and placed in a Soxhlet extraction thimble. Glass wool was placed on the top of the sample and the thimble was placed in a 100-mL Soxhlet extractor. The extractor was wrapped in aluminum foil in order to protect vitamin E from light and to minimize cooling. The sample was extracted with Hex containing BHT (1 mg per 125 mL) in the Soxhlet extractor placed in a water-bath (90 °C) for 4 h. Similar procedures have been employed in HPLC methods for the determination of Ts in pecans (132) and fruit. (133)

SFE is an extraction technique which exploits the solvent properties of fluids above their critical point. Carbon dioxide is often used instead of the organic solvent that is normally employed in conventional extraction methods. The extraction conditions are related to the relative
solvent strength which, in a given fluid, is primarily dependent upon its density. This method can eliminate harmful organic solvents in the extraction of lipophilic plant components and avoid environmental pollution. Marsili and Callahan\(^\text{134}\) compared a liquid–solvent extraction technique with SFE for the determination of \(\alpha\)- and \(\beta\)-carotene in vegetables. They concluded that SFE provides recoveries of \(\alpha\)- and \(\beta\)-carotene from vegetables that are equal to or greater than those obtained with traditional solvent extraction techniques.

The direct solvent extraction of the fat-soluble vitamins from the sample matrix with a suitable solvent system provides a milder environment than alkaline hydrolysis and maintains esterified vitamins in their original form.\(^\text{35}\) Solvent systems must be capable of penetrating tissues and breaking lipoprotein bonds to free the analytes.\(^\text{2}\) Hex is commonly used as the extraction solvent. Other useful solvents include diethyl ether, ethyl acetate and various solvent mixtures. Thompson and Hatina\(^\text{113}\) presented a solvent extraction method for Ts and T3s in foods. Samples (10 g) of foods and tissues were homogenized in IPA and acetone. Low-polarity lipids were obtained in the epiphas after the addition of Hex and water to the filtered extract. After separation, the hypophase was evaporated twice with Hex and the combined epiphases were evaporated. The efficiency of the procedure was \(\geq 97\)% depending on the matrix being extracted. This method has been used by many investigators for vitamin E extraction from a wide array of natural products.\(^\text{5}\)

Ultraviolet/visible (UV/VIS) and fluorescence detectors have been used extensively in food analysis to quantify fat-soluble vitamins. EC detection has been used mainly in procedures using RPHPLC. The major reason for this includes the poor solubility of most electrolytes which are used for conductivity in organic solvents and the incompatibility of organic solvents with some commonly used working electrodes.\(^\text{135}\)

Absorbance UV/VIS measurement represents the most widely used detection method employed in HPLC, and it can be performed using either a fixed-wavelength photometer or a continuously variable wavelength [photodiode-array (PDA)] detector. Although the detector PDA shares many elements with the UV/VIS detector, the essential difference is that it can record the entire spectral range (190–800 nm) during analysis, thus monitoring the chromatogram at selected wavelengths while recording the spectra of eluates simultaneously. Therefore, it eliminates the need to generate multiple chromatograms at different wavelengths and/or collecting fractions to record spectra later. This ability significantly reduces the time taken for analysis.

Fluorescence detection (FLD) is considerably more sensitive than UV/VIS detection.\(^\text{136–139}\) The sensitivity of FLD depends, in part, on the composition of the mobile phase. For example, \(\alpha\)-T and retinol display a 5–6-fold decrease in intensity on changing from Hex to acetonitrile–water (50:50);\(^\text{137}\) hence normal-phase HPLC provides greater sensitivity for FLD than reversed-phase systems.\(^\text{140}\) Caution has to be taken to avoid quenching (reduced intensity of fluorescence) when FLD is used. The factors leading to quenching are (1) dissociation of molecule by the excitation wavelength, (2) absorbance of emitted light by other molecules or the sample itself and (3) collisions of molecules. FLD is also more selective than UV/VIS detection because two wavelengths are required in the measurement and the structural features necessary for a molecule to fluoresce are more limited. Most lipids, including glycerides and sterols, do not fluoresce.\(^\text{35}\) Therefore, injection of fat extracts can be made directly on silica column, for the analysis of vitamin E.\(^\text{5}\)

Ueda and Igarashi\(^\text{141}\) studied the application of EC detectors for detection of Ts in feeds by HPLC. They found that EC detection had a 20-fold higher sensitivity than FLD; however, \(\beta\)- and \(\alpha\)-T cannot be separated owing to the required use of reversed-phase chromatography, because the EC detector needs a conducting eluent. Other examples of the use of EC detection include work by Schneiderman et al.\(^\text{142}\) on the determination of retinyl palmitate in cereal products, by Dionisi et al.\(^\text{143}\) on the assay of olive oil for Ts and T3s and by Huang et al.\(^\text{145}\) on the analysis of vitamin A and vitamin E in plasma. Some selected HPLC methods for determination of fat-soluble vitamins are given in Table 5.

### 4.2 Multianalyte Methods

Development of vitamin assays that can simultaneously quantify two or more analytes has been an important part of method development in food and biological chemistry. Multianalyte methods save time and resources. Simultaneous vitamin assay method development faces the following areas of difficulty, as summarized by Eitenmiller and Landen:\(^\text{5}\)

1. often fat-soluble vitamins are present in nature as multiple, structurally related compounds;
2. the presence of synthetic forms or metabolites can complicate quantitation;
3. each fat-soluble vitamin has its own spectral characteristics and therefore multiple detectors or programmable detectors are required;
4. stability differences among fat-soluble vitamins often complicate extractions;
5. concentrations of the various vitamins differ considerably in biological materials, pharmaceuticals, foods, feeds and fortified products;
Table 5: Selected HPLC methods for fat-soluble vitamins in foods\(^{a,b}\)

6. co-eluting interferences often lead to the need for specialized sample cleanup approaches.

Therefore, there is no single method that can be used to analyze all the fat-soluble vitamins, their synthetic forms and metabolites. However, many good multivitamin methods have been developed with the improvement of modern instrumentation. They are summarized briefly in Table 6.

Water determination in foods is a deceptively simple theme. Defining the quantity to be measured identifies the inherent complexity. Three separate types of measure may be appropriate: a gravimetric measure; a measure related to vapor pressure; and a measure of classes of water. The ubiquitous nature of water in our environment provides additional complexity in the challenge of preventing transfer of water between sample and environment. The earliest measures of amount of water were all gravimetric, determining the weight fraction of water in the food. These methods range from simple direct weighing using a difference technique, to more complex methods where the amount of water is determined by spectroscopic methods or by chemical assay. A wide range of methods have been developed and are in daily use because gravimetric water content is important for formulation and for labeling purposes. This measure, however, is of little value for the prediction of the stability of a food, even though water plays a critical role in determining the stability characteristics of foods. For a measure of the amount of water relevant to stability concerns, the vapor pressure or its related thermodynamic parameters is more relevant. Determination of vapor pressure uses methods developed from thermodynamic roots, although if the product is not at true equilibrium the measured quantity is not a thermodynamic descriptor of the product but it is still a measure of a product characteristic. Rather than describing necessarily the thermodynamic state of the water in the food, these measures all determine the vapor pressure of the atmosphere in contact with the food. Whether this is the equilibrium vapor pressure, and therefore the thermodynamic description, has to be established on a case by case basis. The vapor pressure per se is an important parameter. Vapor pressure can be measured directly in a manometric system or can be inferred from the dew point temperature (at which the relative humidity just reaches 100%). It can also be inferred from the electrical characteristics of sensors that have electrical conductance or capacitance that is a function of the relative humidity of their immediate environment, once sensor and immediate environment are equilibrated.

A special set of applications measure both the gravimetric water content and the vapor pressure that corresponds to this water content. The result is a sorption isotherm. In this case, as an alternative to measuring the vapor pressure, a stable, known vapor pressure can be established and the product allowed to equilibrate to constant weight. The establishment of an atmosphere of known vapor pressure/relative humidity is the essential component of isopiestic techniques. On the assumption of equilibrium, analysis of sorption isotherms according to various models can lead to categorizing various classes of water and identifying the amount of water in each class. Spectroscopic measurements can also lead, more directly, to the identification of the amount of water in different classes. Many different labels, such as bound water, unfreezable water and restricted water, are attached to the categories of water, depending upon the method used to distinguish between the classes. For direct and indirect estimation of vapor pressures it is critically important that the temperature of the sample be stable and accurately known, and also that the temperature in the region where the measurement that will translate into vapor pressure is to be made is accurately known. This is because the driver for many properties that depend upon water content is the relative vapor pressure, and the vapor pressure of pure water has a steep dependence.
upon temperature. It is also important that sufficient time be taken to allow for the establishment of a uniform and steady vapor pressure throughout the vapor spaces of the system, otherwise moisture transfer will occur, driven by the pressure gradients, changing the characteristics of the materials.

1 INTRODUCTION

The theme of “water determination in foods” is deceptively simple. It is necessary as a first step to define the quantity to be measured. This immediately leads us to the inherent complexity of the topic. The amount of water can be identified through the use of three separate types of measure: a measure of the gravimetric quantity of water; a measure of the thermodynamic impact of the water; and a measure of the amounts of water that fall into different classifications. Because water is a ubiquitous component of our environment, there are significant challenges in preventing the transfer of water to or from the sample under study. This results in additional complexity in many of the measurement systems, in an attempt to get a clear and repeatable definition of the sample and of the conditions of measurement.

Historically, the earliest measures of amount of water were gravimetric measurements: the weight fraction of water in the food. Although this is a useful quantity to determine, its value in understanding such factors as the stability of the food and the susceptibility to microbial attack is very limited. Pioneering publications by Scott\(^\text{1,2}\) underlined the importance of a thermodynamic characterization of the “effective amount of water”, otherwise termed water activity. This is essentially a description of the amount of water by a measure of the equilibrium vapor pressure of water in the atmosphere in contact with the food, in contrast to a measure of the weight of water in the food. The information that we seek is often the water activity at a known gravimetric water content, hence there is a need to determine both water activity and moisture content. Descriptions of systems designed for this purpose are given by Gal\(^\text{3,4}\) in a discussion of methods for the determination of sorption isotherms. A schematic of a typical system is shown in Figure 1, and a typical shape for a sorption isotherm is illustrated in Figure 2. In recent years, attempts to understand the dependence of the properties of foods in terms of their water contents, whether defined as gravimetric water content or as water activity, have led to models that categorize the fractions of water that appear to have different properties. This led to such measures as unfreezable water, bound water, etc. Sorption isotherms, for example, have been analyzed, using

\[ \frac{p_w}{p_w^0} \]

models, to arrive at estimates of the amount of water in different categories as indicated in Figure 2, which
identifies ranges for different moisture categories. Allocation of boundaries is qualitative at best. In more general terms, identification of different categories can be seen as identifying the amounts of water that have molecular mobilities in certain ranges. Clearly solid and liquid (i.e. unfrozen) is a simple division, but how liquid is liquid? More complex divisions can be made. Modern advances in spectroscopic techniques allow for the estimation of molecular mobilities and for the quantification of the amounts of water in various mobility classifications. In recent years, categorization of water mobilities has become an important descriptor of the state and amount of water in foods. It must be realized, however, that the range of molecular mobilities is a continuum, and any separation into categories is in some way arbitrary.

This article will discuss the means of estimating gravimetric water content and also water activity. It will conclude with a brief discussion of water mobility, etc.

1.1 Special Precautions Required for Meaningful Measurement

Water is a ubiquitous component of our environment. Exchange of water between materials in contact is common. Atmospheric moisture may be picked up readily by a material if the conditions are favorable. Similarly, moisture may be lost readily to the atmosphere if the conditions are favorable. Because moisture is so readily exchanged, it is important to define the conditions of measurement and to define the state of the sample if a meaningful measure of water content is to be made and reported. It is appropriate to discuss methods of equilibration, of sample collection and the handling required to maintain a sample in a defined condition. The precautions required are dependent upon the particular measure of moisture content that is to be made. For gravimetric determination, it is important that no moisture be gained or lost from the sample, once it has been collected for assay. For vapor pressure measurement, it is important that the amount of moisture that transfers to establish the vapor pressure in the measuring space does not cause a significant change in the equilibrium vapor pressure. It is also important for the temperature to remain constant, because the saturation vapor pressure of water is very temperature dependent. Because of the temperature dependence of vapor pressure, temperature control is an important aspect of moisture measurement. Although absolute vapor pressure is very much temperature dependent, equilibrium relative vapor pressure, is much less dependent upon temperature. Thus, for measurement of relative vapor pressure, the uniform temperature is necessary, whereas for measurement of absolute vapor pressure a precise uniform temperature should be established. The significance of this is that if a sample is in contact with an atmosphere of constant relative humidity, then maintenance of a uniform temperature is sufficient for a defined equilibration, whereas for a sample in contact with an atmosphere of maintained vapor pressure it is necessary to establish a precisely known temperature.

2 GRAVIMETRIC WATER CONTENT

Gravimetric water content describes a measure of amount of water in terms of the weight of water in a given weight of sample. It may be determined directly or indirectly. Care has to be taken to prevent loss or gain of moisture once a sample has been taken. Both the Association of Official Analytical Chemists (AOAC) and the American Association of Cereal Chemists (AACC) publish recommended methods for moisture determination. Bradley[10] discusses methods for the analysis of moisture and total solids in some detail.

2.1 Methods of Sample Handling

The general procedures for sampling and sample handling prior to gravimetric estimation of water content are similar to those for most analytical protocols. Sampling procedures are required that give a statistically valid sample. After the sample is taken, it must be protected from contamination and from change. Also, the sampling procedure itself, namely any methodology to mix, subdivide or reduce particle size, must have minimal impact upon the sample composition. General sampling procedures are discussed in most textbooks of food analysis, e.g. that of Pomeranz and Meloan. As indicated above, special precautions are required to minimize inadvertent loss or gain of moisture during handling. Exposure to an open atmosphere must be minimized. The rate of moisture exchange is related to the relative humidity of the atmosphere. Only exposure to controlled atmospheres for the purposes of controlled moisture exchange in a well-developed protocol is acceptable. Excessive heating during grinding must be minimized because this increases the risk of moisture loss. The headspace of sample storage containers must also be minimal, because moisture will equilibrate between the sample and the headspace. The preferred storage container should be airtight, with a hermetic seal, to minimize the possibility of moisture exchange with the environment.
2.2 Oven Drying Methods

In order to determine moisture content, a sample of known initial weight may be heated in specified conditions and the loss of weight determined. The results are dependent upon the type of oven used, the time and temperature of drying, and the characteristics of the product. Such methods are simple and direct, and can allow for simultaneous analysis of a large number of samples. Care is required to ensure that the samples cannot pick up significant moisture between drying and weighing. The rate and extent of moisture removal increase as temperature increases. Pure water boils at 100°C at sea level. Dissolved solute raises the boiling point, so that as moisture is removed the boiling point increases. This makes it more difficult to evaporate additional moisture under constant temperature conditions. The level of drying that can be achieved is then dependent upon the drying temperature. At higher temperatures, more moisture can be removed. However, as the drying temperature increases, loss of other volatile components also increases, somewhat negating the advantage in terms of moisture removal. Also, at higher temperatures the extent of thermal degradation increases. Weight loss due to thermal degradation and loss of volatile materials is a source of error that should be minimized, so the choice of drying temperature is dependent upon sample type. Frequently 130°C is recommended for air ovens and 100°C for vacuum ovens. For more sensitive materials, such as fruits, the corresponding temperatures are 100°C and 70°C. The recommended temperature for drying will often be recommended in a specified procedure for the commodity. Because the boiling point of water is pressure dependent, reducing the environmental pressure by using a vacuum oven makes removal of moisture easier. Volatile substances are also removed more easily, but the extent of thermal degradation is reduced. Drying ovens are available from a wide range of manufacturers, and frequently come with detailed instructions for their use and clear indications of their suitability for different product types. All drying ovens must be protected from moisture ingress, hence any air streams entering the oven must be passed through an air dryer.

2.2.1 Convection/Conduction Ovens

As a consequence of the different characteristics of different materials, the oven drying methods recommended by, for example, the AOAC and the AACC specify both drying temperatures and times. These require careful control. The uniformity of temperature in the oven must also be considered. The three most common oven types are convection ovens, forced draft ovens, and vacuum ovens. The convection oven exhibits the greatest internal temperature variations and a 10°C variation is not uncommon. This influences the attainable accuracy, because the location of a sample in the oven will influence drying rate and drying efficiency. This type of oven is not suited to precise measurement. Forced draft ovens maintain temperature differentials of less than 1°C. These are suited to much higher precision of measurement of moisture loss. Vacuum ovens are intermediate in temperature uniformity but have the advantage of allowing more water removal at much lower temperatures, thereby minimizing thermal degradation. Heat transfer in a vacuum oven cannot be through convection or forced draft of an atmosphere, because the atmosphere density is much reduced. The heat transfer must be through the structural framework. This must be taken into account when choosing materials for the sample containers.

The design of the pan that holds the sample influences the ease and precision of measurement. Pans may be reusable or disposable. The costs of cleaning reusable pans can be significant. Covers should be utilized, because their use helps to prevent loss of sample through spattering. However, it is important that the cover design and positioning should not hinder evaporation. For most work, it is recommended that disposable aluminum pans be used, with fiberglass covers. A metal pan enhances thermal conduction to the sample, which is especially important in a vacuum oven. Fiberglass is preferred over metal for the cover, because metal covers can hinder evaporation. A fiberglass cover allows for evaporation, while preventing loss of solids content through spattering. If metal covers are used, their position must be adjusted prior to drying to allow for moisture removal. Both pans and covers should be thoroughly predried before use, and should be handled with tongs to prevent inadvertent contamination. Samples should be transferred rapidly into the pans and weighed immediately. After drying, pans must be handled in a very dry atmosphere prior to reweighing, because dried samples will rapidly pick up moisture. The appearance of the sample should be noted. If there is evidence of crusting or lumping, which leads to erratic drying, it may be necessary to use the sand pan technique, where the sample is mixed with a preweighed amount of dried sand in the pan to help prevent clumping and crusting and lead to more uniform and complete drying.

Drying may be performed either for a preset time or until two successive weighings of the drying sample show no significant weight change. For convenience, most standard methods define a time that will have been determined by experiment to be sufficient for effective drying. As indicated, both the AOAC and AACC methods give precise details as to the protocols for different types of materials and also for different types of oven. For vacuum ovens, in addition to specifying
temperature and pressure, a controlled rate of dry air purge is required in defined methods.

2.2.2 Infrared Drying
The use of radiant (infrared) heating can shorten drying times compared to convection or conduction heating in the conventional drying oven. However, it results in significant temperature gradients and a greater probability of thermal degradation. Surface temperatures can reach over 200°C. This method is most suited to rapid qualitative process monitoring. If used in a vacuum oven system, infrared heating enables more rapid evaporation. The lower pressures and hence lower temperatures also help to reduce the amount of thermal degradation compared with conduction drying. The method should be confirmed by use of calibration standards on a regular basis. Equipment is available from many sources.

2.2.3 Microwave Drying
An alternative method to conductive, convective or radiant heating for energy transfer to the sample employs microwave energy. Specially designed microwave oven systems are widely available for moisture content assays. These have the advantage of ease of use and often ease of automation. The input power can be controlled readily but the energy pattern is very much dependent upon oven design. The sample, too, can influence the heating pattern. Standard methods exist for different materials that specify the particular oven to be used. The usual procedure is for the internal balance to be tared with fiberglass pads, the sample to be placed rapidly between the pads, and power applied to dry the sample. Sample weighing is continuous. Care is needed in sample placement to ensure uniform heating and to prevent localized charring. The method is suited for high throughput but does not lead to high precision. Each design of microwave oven has a unique heating profile, and, as a consequence, standard methods (e.g. AOAC Method 977.11 for cheese) specify the model of oven employed. Calibration against a vacuum drying procedure is required (e.g. AOAC Method 926.08 for cheese).

As already indicated, commercial drying ovens from a range of manufacturers are available for all of the above methods. These ovens come with detailed instructions for use. Most recently, microwave ovens and radiant heating ovens seem to have captured the largest market share due to their ease of use and rapid sample throughput, but the need to confirm their reliability by use of standardization procedures must be borne in mind.

2.3 Distillation Methods
Distillation methods also fairly directly determine water content and are defined as standard methods. For example

AOAC Method 969.19 defines a distillation method to determine the moisture content of cheese. These methods involve the co-distillation of water in a food sample with a high-boiling solvent immiscible with water. Because the water that co-distills is immiscible with the solvent, its volume can be determined easily. Direct and reflux distillation methods may be used. In direct distillation, the sample is heated in a high-boiling solvent at a temperature well above the boiling point of water, and the resulting vapors are condensed and collected. In reflux methods the solvent is re-circulated so that extraction can be more efficient. Lower temperatures can be effective. Special traps have been designed to prevent contamination and moisture pick-up. A typical distillation assembly is shown schematically in Figure 3. There are several sources of error associated with this type of method.

2.3.1 Errors Associated with Distillation Methods
Because these methods are predicated upon immiscibility of water and solvent, any event that prevents the water and the solvent from separating can lead to errors in estimation of water volume. Typical problems include water droplets sticking to surfaces in the apparatus and failing to merge with the main volume of water. Also, the formation of emulsions leads to entrainment of water
in the solvent, unless the emulsions can somehow be broken. Another source of error is chemical reactions that produce water through degradation of components of the sample. These can be minimized by reducing the temperatures required for co-distillation.

2.4 Chemical Methods

A potential disadvantage of drying or distillation methods is that the water content is not determined directly as such, but rather it is inferred from a weight change or from a volumetric measurement. Loss of volatile substances and degradation can lead to weight change. Soluble contaminants and partitioning of partially soluble components between phases can influence volume change. As an alternative to these methods, chemical methods are available to determine the amount of water by evaluating the extent of a chemical reaction. As such, the sources of error and the limitations are different. The most widely applicable chemical method is the Karl Fischer titration.

2.4.1 Karl Fischer Titration

This method does not require sample heating and so does not lead to thermal degradation. It is particularly effective for low-moisture foods. It is based on the reduction of iodine by sulfur dioxide in the presence of water, according to Equation (1):

\[
2\text{H}_2\text{O} + \text{SO}_2 + \text{I}_2 \rightarrow \text{H}_2\text{SO}_4 + 2\text{HI} \quad (1)
\]

In order to dissolve the iodine and sulfur dioxide, methanol and pyridine are used as solvents. The resultant reaction scheme is shown by Equations (2) and (3):

\[
\text{C}_5\text{H}_5\text{N} \cdot \text{I}_2 + \text{C}_5\text{H}_5\text{NSO}_2 + \text{C}_5\text{H}_5\text{N} + \text{H}_2\text{O} \\
\rightarrow 2\text{C}_5\text{H}_5\text{N} \cdot \text{HI} + \text{C}_5\text{H}_5\text{N} \cdot \text{SO}_3 \quad (2)
\]

\[
\text{C}_5\text{H}_5\text{N} \cdot \text{SO}_3 + \text{CH}_3\text{OH} \rightarrow \text{C}_5\text{H}_5\text{N(H)SO}_4 \cdot \text{CH}_3 \quad (3)
\]

For each mole of water, 1 mol of iodine, 1 mol of sulfur dioxide, 3 mol of pyridine and 1 mol of methanol are used. Two detection methods can be used. The volumetric titration adds the reagents to the sample in a closed container, isolated from atmospheric moisture. Excess, unreacted iodine can be detected visually or potentiometrically. This procedure is effective for samples with moisture content in excess of 0.03%. At lower moisture levels, a coulometric titration is preferred. Here, the reagent iodine is produced electrolytically, to titrate the water. The amount of iodine required to titrate the water is determined from the current needed to generate it.

The volumetric titration may be direct, adding the Karl Fischer reagent as a titrant directly to the sample, or it may be indirect, extracting water from the sample into a solvent such as methanol and then titrating the methanol extract.

Standardization of the reagent is necessary before the amount of water can be determined. Because the reagent is not stable, this must be performed before each use. Standardization requires a standard of known water content. This can be pure water, a solution of water in methanol, or sodium tartrate dihydrate (or some other characterizable hydrate). Pure water is not an easy standard to employ, because of the difficulty in precisely measuring small amounts. A standard solution of water in methanol can slowly change with time, due to absorbing atmospheric moisture. Sodium tartrate dihydrate is quite stable and is the standard of choice.

2.4.1.1 Sources of Error in the Karl Fischer Titration

Although the Karl Fischer titration is an effective method for the measurement of water content, there are several sources of error that must be taken into account. Incomplete extraction of water from the sample can lead to error. To enhance water extraction, the fineness of grinding can be important. Other errors involve contamination by water from sources other than the sample. Because the method is a very sensitive measure of moisture, external air must be prevented from access to the reaction chamber, or else atmospheric moisture will be absorbed. All glassware and tools must be dried rigorously before use in order to prevent inadvertent addition of moisture. In addition to ensuring carefully that all the water in the sample and only the water in the sample is determined, it must be realized that substances other than water may react with the assay reagent. Thus, certain interferences must be recognized. The most important of these are from ascorbic acid, which is oxidized by Karl Fischer reagent, from carbonyl compounds, which react with methanol to form acetics and water, and from unsaturated fatty acids, which react with iodine.

Given the unstable nature of the reagent, the difficulties that are experienced in its preparation, and the critical requirement for preventing access to atmospheric moisture, it is best to employ one of the many systems that are available from instrument manufacturers. Although the principles of operation are common, the details of operation differ from one supplier to another.

2.4.2 Alternative Chemical Assays for Water

Although there are other chemical methods for determining water, such as the use of calcium carbide, which releases acetylene on reacting with water through the reaction depicted by Equation (4):

\[
\text{CaC}_2 + 2\text{H}_2\text{O} \rightarrow \text{Ca(OH)}_2 + \text{C}_2\text{H}_2 \quad (4)
\]
these are of limited application and difficult to use with any precision. The Karl Fischer reaction is the only chemical method with wide application.

2.5 Indirect Methods of Water Content Determination

So far, only fairly direct methods for estimating the gravimetric water content have been described. These all tend to be demanding of technique, and are slow. Indirect methods exist for estimating water content. These rely on careful calibration for particular materials against the direct methods described above. Common indirect methods require the measurement of some easily determined property of the food material and then application of a calibration chart to estimate the appropriate water content. For an indirect method to be successful, the relationship between water content and the property must be repeatable, and the change in property with water content should be such that the method is sensitive to small changes in water content.

2.5.1 Infrared Spectroscopy

Water can be determined by measuring absorption at infrared wavelengths characteristic of the absorption frequencies of water. Typical wavelengths are 3.0 and 6.1 µm (fundamental vibrational mode), 1.93 µm (combination) and 1.45 µm (first overtone OH stretch). Samples for evaluation must be thin, for transmission measurements. An alternative to using a thin sample is to disperse a finely divided sample in a suitable carrier fluid before performing a transmission measurement. Reflectance measurements characterize the surface region more than the entire sample. Generally, infrared absorption is calibrated by using samples of known moisture content, and wavelengths for measurement are chosen to minimize interferences. Fourier transform spectrometers collect data for all wavelengths by interferometry, followed by mathematical transform. This is a more rapid procedure than the wavelength scanning of a dispersive instrument. It is necessary to correlate the infrared spectrum with water content data obtained by more direct measurement techniques. Modern computers make this a simple task, but care should be taken to confirm that the wavelengths identified by the correlation routine are significant in terms of the spectroscopic absorbance of the sample. 

2.5.1.1 Near-infrared Spectroscopy

Near-infrared reflectance measurements can be applied to the estimation of water content. Once again, this is a method in which data sets are correlated for samples of differing water contents, and the resulting correlation equations are then used to estimate the water content of suitable samples. Although early instruments utilized only two wavelengths, this was unduly influenced by factors such as particle size. More recent work uses at least three wavelengths: two reference wavelengths and a measuring wavelength. For a measurement to be reliable, it is important that the sample is equilibrated. For many samples, the extent of absorption is a linear function of moisture content. Further improvement in accuracy comes from measuring near-infrared reflectance at a wider range of wavelengths. Calibrations employ mathematical analysis of the entire data set by multi-variate statistics. As computer power continues to increase, this method becomes more and more effective and is of increasing popularity. It is essential that it be calibrated against a standard gravimetric procedure before being applied as routine.

2.5.2 Electrical Properties

The electrical properties of many systems vary in a repeatable fashion with water content, making such properties suitable as indirect probes of water content.

2.5.2.1 Electrical Conductivity

Measurement of electrical conductivity is simple and rapid. Samples are prepared with specific geometries between measuring electrodes. This can be through pressing a standard mass of sample into a cup with preconfigured electrodes. Alternatively, it can be the sectioning of a sample to fit between electrodes, or the insertion of an electrode jig into a sample of controlled density. In all cases the conductivity or resistance is measured using standard electrical methods. The moisture content is obtained from a calibration curve generated from samples of the materials that have had their moisture content determined by conventional measurement. The AOAC methods that exist for dried fruits utilize electrical conductivity.

2.5.2.2 Electrical Capacitance

Sample preparation for electrical capacitance measurement is very similar to that for electrical resistance measurement. The methods differ in that the measurement performed is of the capacitance between the electrodes. These measurements can be made at a range of frequencies. Measurement of capacitance is based on the fact that the dielectric permittivity of water is much higher than that of most other fluids or solvents. The variation in capacitance with frequency can lead to information about the environments experienced by water in the sample. Once again, for estimation of moisture content, calibration curves must be established for the particular material under investigation.

For both electrical methods, it must be realized that the solid composition of the sample will influence the calibration curve. In particular, the ratios of salts to nonelectrolytes will have a significant influence on the correlations between water content and electrical
conductivity and electrical capacitance. The value of these methods is very much linked to the effectiveness of the calibration procedures that are followed.

2.5.3 Estimation of Soluble Solids

Certain properties of aqueous solutions are dependent upon the solute concentration. In appropriate cases it is possible to estimate the moisture content of a food by estimating the concentration of soluble solids. This requires that the ratio of the content of soluble to insoluble solids is known or can be estimated. Given the concentration of soluble solids, the amount of water can be calculated by difference. Easily measured properties that can be used to estimate the concentration of soluble solids include refractive index, solution density and freezing point. Refractive indices are often utilized to estimate the content of soluble solids in many fruits, fruit products and sugar solutions. The use of a simple refractometer, such as an Abbe refractometer, allows for the determination of the refractive index of the solution. Rather than reading the refractive index, the instrument scale is calibrated to read the Brix of a sugar solution that has this refractive index. A range of AOAC methods exist, e.g. AOAC Method 970.59, which utilize refractometry to determine soluble solids and hence, by inference, the moisture content. Measurements of density, utilizing pycnometers, hydrometers or specific gravity balances, are often used for milk products, beverages, pickling brines and sugar solutions. Once again, the density correlates directly to the solute concentration of the solution under study, as long as the principal solutes are known in advance. Freezing point measurements are often used to check for adulteration of milk.

2.6 Thermogravimetric Analysis

One further gravimetric method should be mentioned: the method of thermogravimetric analysis. A small sample attached to a weighing sensor is heated through a preset temperature program, and the changes in weight are followed. Loss of moisture and other volatile materials is readily seen, as is thermal degradation of the sample. A typical thermogravimetric analyzer scan is shown in Figure 4. This technique can help to identify the appropriate range of temperatures for drying procedures. The temperature at which thermal degradation sets in can often be seen clearly on the thermogravimetric trace.

2.7 Solvent Extraction

In describing the Karl Fischer method, passing reference was made to using an extraction solvent for removal of water. This provides yet another route for the determination of water content. Provided that extraction of water by the solvent is quantitative and complete, then the task becomes determination of the water content of the extraction solvent. With a suitable solvent, this can be achieved through the use of gas chromatography. This requires a liquid or gaseous sample, which can be introduced into the column. Determination of water will be effective only if extraction into the solvent is quantitative and if there are no substances extracted that will provide interference. After extraction, the gas chromatography system is used to determine the moisture content of the extraction solvent, from which the moisture content of the original food can be determined. A typical protocol is to take 15 g of sample and blend with 100 mL of solvent (e.g. 95% absolute methanol and 5% secondary butanol). After the mixture has settled for 20 s, a 2-µL aliquot of the clear supernatant is analyzed using a gas chromatograph. Calibration samples are solvent with known amounts of water added. The method is applicable to a range of foods with moisture contents varying from 8 to 60%.

The advantage of indirect methods, and many correlation procedures, is that, unlike the direct determination of moisture content, the indirect method may be rapid and simple, allowing for the monitoring of a large number of samples. The methods are also often conducive to automation. However, the value of any procedure is dependent on the robustness of the correlation of the property determined to the moisture content, and also on the quality of the original data used to establish the correlation equations. Care must be taken to establish a calibration that is reliable.
WATER DETERMINATION IN FOOD

3 WATER ACTIVITY (OR EQUILIBRIUM WATER VAPOR PRESSURE)

Although gravimetric water content is an important parameter, a thermodynamic measure of “amount of water” is more appropriate for describing the potential of water to participate in chemical and physical processes. Activity – a thermodynamic measure of “quantity of substance” – was defined by Lewis and Randall.\(^{(14)}\)

“Activity is, at a given temperature, the ratio of the fugacity, \(f\), of a substance in some given state and its fugacity, \(f_o\), in some state which for convenience has been chosen as a standard state”. When a vapor behaves in a manner close to ideality, the fugacity is closely approximated by the partial vapor pressure. A common standard state is the pure liquid. For most practical purposes, water activity is defined as the ratio of the equilibrium partial vapor pressure of water above the sample to the equilibrium vapor pressure above pure water at the same temperature. The equilibrium partial vapor pressure of water over the sample, \(p_{w,m}\), may be measured directly or determined indirectly. The saturation partial vapor pressure of water at the same temperature, \(p_{o,w}\), can be obtained from tables if the temperature is known. Great care must be taken to ensure that equilibrium conditions have been established within the sample, and between the sample and its atmosphere, because a measure of a transient partial vapor pressure is of little value. True equilibrium is seldom seen in foods, but a measurement made at steady-state conditions can convey important information. It is important either that the whole measuring system be at a uniform temperature or that the temperature of the sample be precisely known. In some measuring systems, the sensor that determines the vapor pressure may not be at the same temperature as the sample. In this situation the temperatures of the sample environment and the sensor environment must be known precisely. Leung\(^{(15)}\) and Chirife\(^{(16)}\) provide useful discussions of the applications of relative vapor pressure/water activity information. Levine and Slade\(^{(17)}\) organized a meeting at which many of the relevant issues have been discussed.

3.1 Vapor Pressure Manometer

This entails the direct measurement of the partial vapor pressure above a sample of known water content. Temperature control of the sample is critically important, because the saturation vapor pressure of water and the equilibrium partial pressure above an aqueous solution change by about 5% for every 1° rise in temperature around 25°C (see Table 1). A typical vapor pressure manometer system is illustrated in Figure 5. Although a vapor pressure manometer is the most direct method of determination of partial vapor pressure, it is a very demanding technique if good accuracy is to be achieved. Given the dimensions of the system, temperature control is difficult. The presence of other volatiles leads to an erroneous estimate. Exclusion of air is also difficult.

3.2 Dew Point Determination

As with direct measurement of the vapor pressure, this method entails establishing a constant vapor pressure above the sample, with careful temperature control of the sample and its immediate environment. In this case, because the determination of the partial pressure is by

\begin{table}[h]
\centering

\caption{Temperature dependence of the saturation vapor pressure of water (\(p_{o,w}\)) and water activity (\(a_w\)) for selected sulfuric acid concentrations. (Adapted from Rizvi\(^{(21)}\))}
\end{table}

![Figure 5](image_url) Schematic diagram of a vapor pressure manometer. Prior to a measurement, the system must be evacuated and dried. A complex arrangement of valves is necessary to protect the sample while this process is in hand.
Figure 6 Schematic diagram of a dew point cell. The sample is placed in a thermostatically controlled holder. The partial vapor pressure is equal to the saturation pressure at the dew point, measured by the initiation of condensation on the cooled mirror. Condensation is detected by an optical sensor, and the temperature of the mirror, cooled by a Peltier device, is recorded. The vapor spaces are kept to the minimum necessary. Except for the sensor, other electrical devices for measuring $a_w$ are of similar layout, as described in the text.

Determination of the dew point temperature by use of a cooled mirror surface is a fairly direct method for determination of the partial vapor pressure of the water. Alternative methods to estimate partial water vapor pressure exist. In the schematic of Figure 6 the dew point sensor could be replaced by alternative sensors that respond in some predictable fashion to the water vapor pressure of their surroundings. The generic cell design can remain the same as illustrated in Figure 6, except that now the region of the sensor also must be maintained at a uniform, known, temperature rather than be adjusted to the dew point. Recalling the discussion of sorption isotherms, and also the indirect methods for arriving at moisture content, it is clear that the physical characteristics of many systems are dependent on moisture content and the associated water activity. If a material has a repeatable sorption isotherm, then establishing the dependence of some property on moisture content/water activity allows for its use as a vapor pressure sensor. If the temperature of the sensor is known and sufficient time is allowed for the sensor to equilibrate with the atmosphere around it, then measurement of the property in question allows for estimation of the water activity $a_w$ of the sensor and hence the $p_w$ of the atmosphere adjacent to the sensor. In a well-designed system, this $p_w$ will also be the partial vapor pressure of water close to the sample. Given that the sample is at uniform temperature and that equilibration has been achieved, this allows for estimation of the equilibrium partial vapor pressure of water above the sample at the temperature of the sample. Because the sample temperature is known, $p_w$ can be obtained from tables. If the whole system is at a uniform temperature, then $a_w$ of the sensor is $a_w$ of the sample. It is not necessary to establish a uniform temperature throughout the chamber: it is only necessary to establish uniform, known, temperatures in the region of the sample and in the region of the sensor, provided that the sample is the only significant source of water vapor.
3.3 Water Activity Sensors

Further to the preceding discussion, by “water activity sensors” we mean those sensors that, when equilibrated with an atmosphere of known equilibrium relative humidity (or water activity), establish a stable water content. Stated differently, these are materials with highly repeatable sorption isotherms. Measurement of a property that depends upon water content then allows for identification of the equilibrium relative humidity of the atmosphere in contact with the sensor and, because the temperature at the sensor is known, the actual vapor pressure of the atmosphere.

3.3.1 Electric Hygrometers

As indicated earlier, the electrical properties of materials are dependent upon their water contents. This can be utilized to provide sensors that change in properties according to the relative humidity of the atmosphere to which they are exposed. For an effective sensor, the sorption isotherm (water content versus water activity) will be reproducible, and the dependence of measured property to water content will be a monotonous function. It has been found that electrical conductance and electrical capacitance for many substances are monotonous functions of water content at a defined temperature. Because these are measured readily, they provide the basis for a range of sensors. Many commercial designs are on the market, all based on the same principles.

3.3.2 Conductance

Sensors based on this principle measure the conductance of an immobilized film containing a salt such as lithium chloride. The sensor equilibrates, at a known temperature, with the atmosphere above the sample. The relative humidity of this atmosphere determines the moisture content and hence the conductivity of the cell. Using standard samples, which establish atmospheres of known relative humidity, a calibration curve of sensor conductance against relative humidity is established. Several commercial instruments utilize this type of sensor. Early designs were prone to contamination, but modern sensors seem to have good reliability.

3.3.3 Capacitance

The electrical capacitance of a film such as aluminum oxide varies with moisture content. Capacitance is measured readily. A sensor based on aluminum oxide can therefore be calibrated to allow for estimation of the relative humidity of any atmosphere in which it is equilibrated. Once again, there are several commercial instruments that utilize this type of sensor. In some capacitance sensors, a polymer film is utilized rather than an aluminum oxide film. These sensors have proved quite reliable in use.

It should be noted that the sensors described in section 3.3 should all be checked on a regular basis. Solutions of known equilibrium relative humidity should be used to test the operation. Table 2 lists some appropriate saturated solutions. Another list is given as AOAC Table 978.18. To achieve equilibrium relative humidity values other than those of saturated solutions, solutions of measured concentration can be used. Care must be taken to prevent significant change in concentration, because equilibrium relative humidity is sensitive to concentration. Note that, unlike the situation for saturated solutions, for sodium chloride solutions of fixed concentration the water activity is not very dependent upon temperature in the range around 25 °C (see Table 3). As long as sample temperature is known precisely, this makes sodium chloride solution a good calibration standard.

3.4 Measuring Related Thermodynamic Quantities

In addition to measurement (directly or indirectly) of the vapor pressure established in the atmosphere above a sample, other thermodynamic properties that are related to the water activity can be determined. Properties that are influenced by concentration are often termed colligative properties. Two common colligative properties that are related to water activity are osmotic pressure and freezing point depression. Measurement of osmotic pressure is impractical for many food systems, so in general only freezing point depression has been used to estimate water activity.

3.4.1 Freezing Point Depression

The freezing point depression of water, \( \Delta T_f \), is related to water activity through the expression shown in Equation (5):

\[
\log a_w = 0.004207 \Delta T_f + 2.1 \times 10^{-6} \Delta T_f^2
\]  

Determination of freezing point depression requires a sensitive thermometer and also requires that steps be taken to eliminate supercooling. This method is used most frequently to check for adulteration of milk.

3.5 Isopiestic Methods

The methods of determining water activity described so far are suitable for application to samples of defined gravimetric water content. In all cases, such samples are allowed to equilibrate only within the measuring cell. There must be little loss of water from the sample to the measuring cell or from the measuring cell to its environment for valid measurements.

An alternative approach, often used in the generation of sorption isotherms, is to establish above them equilibrium vapor pressures that can be obtained from tables. This vapor pressure is, as indicated earlier (Table 1), dependent upon temperature. The equilibration solutions can be of fixed concentration, establishing an atmosphere of stable equilibrium relative humidity at constant temperature. Provided that uniform temperature is maintained throughout the system, the equilibrium relative humidity (equilibrium relative vapor pressure) does not change much for the small variations in the constant temperature that is maintained. Hence, although equilibration requires elimination of temperature gradients and precise control of temperature, this need not be accurate at the target temperature for valid measurement. It is necessary to have a sufficient volume of the equilibration solution to ensure that the concentration does not change significantly as moisture is taken up by the samples under equilibration. An alternative approach, which maintains constant concentration regardless of water vapor transfer, is to use saturated solutions for equilibration. Here, however, temperature must be known accurately as well as be maintained precisely constant. Not only is the equilibrium vapor pressure above the saturated solution temperature dependent, but now also the equilibrium relative vapor pressure is temperature dependent (Table 2), because saturation solubility is temperature dependent. The advantage of this approach, which may justify dealing with the need for more stringent temperature control, is that as long as excess solute is present, the vapor pressure will remain constant, unaffected by the uptake of water by the samples. The

![Figure 7 Schematic diagram of isopiestic equilibration by solution system. The atmosphere, above a suitable solution (see Tables 1–3) is maintained at constant temperature throughout the enclosure. It may be evacuated prior to equilibration. The sample is exposed to the atmosphere for a sufficient time to reach a steady state. The sample container is readily sealed or opened.](image-url)
challenge in isopiestic measurements is first to equilibrate the samples as rapidly as possible and then to determine the sample weight accurately. Because large numbers of samples may be equilibrated together, some design of sample containers is required that allows for easy access of the equilibration atmosphere, while at the same time allowing for the sealing off of the sample once equilibration is complete, to allow for transfer to the weighing system without too much moisture exchange.

3.5.2 Bithermal Equilibration
An alternative approach to the use of equilibration solutions, which also allows for maintenance of an atmosphere of controlled relative humidity in the equilibration zone, employs the same principle as is used in the dew point method for determining vapor pressure. In this case, the temperature of a reservoir containing pure water is controlled. This establishes a vapor pressure equal to the saturation vapor pressure at that temperature. If a vapor path is provided to an equilibration cell at some higher temperature, the saturation pressure at T1 is established as the pressure at T2. Hence, the relative humidity at T2 is maintained at \( \frac{p_{w}^{T1}}{p_{w}^{T2}} \).

This type of approach is particularly suited to the establishment of sorption isotherms, because the sample can be maintained at constant temperature, attached to some form of balance, and sample weight (and hence water content) can be monitored continuously. By stepwise increase of the temperature of the water reservoir, the water content at increasing relative humidity can be followed. If the reservoir temperature is lowered in steps, the isotherm during desorption can be obtained. Care must be taken to allow for equilibration before moving to the next step. The two chambers must also be able to maintain constant, uniform temperatures within the volume of the chamber. A typical configuration is shown in Figure 8.

3.6 Sorption Isotherms
A variety of systems exist for the measurement of sorption isotherms. Spiess and Wolf\(^{17}\) describe a system recommended by the participants in COST90. This is the best-documented system available. Note, however, that unless the samples studied are very carefully standardized, it is difficult to replicate results from one center to another. The establishment of internal equilibrium is also difficult to achieve. Equipment has become available that allows for the rapid determination of water sorption and desorption on small samples. Sensitive balances can determine small changes in mass. For well-characterized materials, this can lead to valuable information, and indeed the rapid sorption systems are in widespread use in the pharmaceutical industry. In food systems, the ability to identify rapidly a sorption steady state can be useful, and helps to characterize the surface of the material, but the slow process of moisture equilibration in the bulk of a food, and the nonequilibrium nature of many foods, make it difficult to compare results between laboratories.

4 CATEGORIES OF WATER
Both gravimetric water content and water vapor pressure are single points of information. Today, often more detail is requested. Although for many years the measurement of water content, water activity, and their interrelation through moisture sorption isotherms has sufficed to describe water in foods, it is no longer sufficient. In past research, the shapes of sorption isotherms and the equations and models that attempt to fit the sorption isotherm data have been interpreted in terms of classes of water. Fitting of isotherms to equations such as the BET equation led to allocation of amounts of water to various categories. A variety of methods have evolved that estimate water in different environments. There is much discussion as to the applicability of these classifications. Although useful, they tend to obscure the reality that water in foods exists as a continuum, with a gradation of properties of the individual molecules that depends upon individual molecular environments and also reflects the ability of water molecules to exchange rapidly between environments. The many classification
models must therefore be seen as “lumping” models, or arbitrary classifications. Also, it has to be realized that the rapid exchange means that as water content changes, the environments and exchange patterns of all water molecules change. There are no individual water molecules that remain in a particular environment for an extended time, although there may always be water molecules in that environment.

4.1 “Bound” Water

The concept of bound water is rather imprecise. It suggests that water may exist as free (solution) water, or as water in some way restricted by its environment. Variously described, the estimates of “bound” water differ for the same system. Bound water has been described as the water that remains unfrozen at a specified temperature, determined by thermal analysis techniques. It can also be determined by spectroscopic techniques, the most common being nuclear magnetic resonance, where the liquid signal at subfreezing temperatures is interpreted as a measure of the unfrozen water. The topic is covered in great detail in the proceedings of a 1989 meeting discussing water in foods, and in the publications of the ISOPOW symposia.

4.2 Water Mobility

Spectroscopic measurements are influenced by the properties of the solvent water. A variety of models exist that take the time- or frequency-dependent signal from nuclear magnetic resonance, dielectric or other spectroscopic techniques, and derive estimates for the number of water molecules that exist in a variety of categories. The results of these studies may be published in great detail, and many useful correlations have emerged between classifications of water and system properties. It must be realized, however, that all of these results are model dependent, and that, often, different authors have interpreted essentially the same spectroscopic data in widely different ways. The spectroscopic measurement itself is an experimental fact. The interpretation of the data in terms of classes or fractions of water is a hypothesis and requires independent validation by other methods before it can be said to identify real situations.

Forensic Science: Introduction

T.A. Brettell  
New Jersey State Police, West Trenton, USA

Analytical chemistry as applied to forensic science involves the analysis of drugs and poisons, forensic DNA analysis and the analysis of trace evidence.

Drugs and poisons include ethanol and volatiles, cannabinoids, morphine and related narcotics, cocaine, amphetamines, barbiturates and benzodiazepines. Forensic DNA analysis involves the following techniques: DNA extraction and quantification, restriction fragment length polymorphisms, amplified fragment length polymorphisms (Amp FLP), short tandem repeats (STR), gender identification, AmpliType PM and HLA-DQA1 and mitochondrial DNA typing. Trace evidence includes the analysis of paints, fibers, glass, gunpowder and primer residue detection, petroleum products and fire debris, explosives, and the comparison of impression evidence including fingerprints, footwear impressions, and tiremarks.

This wide range of samples, which must be investigated, requires the use of chemical, chromatographic, spectroscopic, spectrometric, microscopic and immunological techniques which are in common with the techniques presented in other sections of this Encyclopedia. These other sections, which present techniques that are utilized or can be utilized in forensic analysis include: Clinical Chemistry, for example see Drugs of Abuse, Analysis of and also Molecular Biological Analyses and Molecular Pathology in Clinical Chemistry; Coatings, for example see Microscopy of Coatings and Atomic Spectroscopy in Coatings Analysis; Environment: Water and Waste, for example see Biological Samples in Environmental Analysis: Preparation and Cleanup; Explosives Analysis in the Environment; Nitroaromatics, Environmental Analysis of; Industrial Hygiene, for example see Metals in Blood and Urine; Biological Monitoring for Worker Exposure; Nucleic Acids Structure and Mapping, for example see Sequencing and Fingerprinting DNA by Hybridization with Oligonucleotide Probes; Polycyclic Aromatic Compounds Mapping: Restriction Landmark Genomic and cDNA Scanning; Sequencing Strategies and Tactics in DNA and RNA Analysis; Petroleum and Liquid Fossil Fuels Analysis, for example see Near-infrared Spectroscopy in Analysis of Crudes and Transportation Fuels; Nuclear Magnetic Resonance Characterization of Petroleum; Pharmaceuticals and Drugs, for example see Nuclear Magnetic Resonance Spectroscopy in Pharmaceutical Analysis; Mass Spectrometry in Pharmaceutical Analysis; Planar Chromatography in Pharmaceutical Analysis; Polymers and Rubbers, for example see Gas Chromatography in Analysis of Polymers and Rubbers; X-ray Scattering in Analysis of Polymers; Pulp and Paper, for example see Fourier Transform Infrared Spectroscopy in the Pulp and Paper Industry; X-ray Photoelectron Spectroscopy, Paper Surface Analysis by; and Mass Spectrometry, for example see Liquid Chromatography/Mass Spectrometry.

There are 14 forensic science techniques presented in the Forensic Analysis section that follows this Introduction. These articles, together with the related articles from other sections cited above, provide a core resource of forensics chemical analysis.

Atomic Spectroscopy for Forensic Applications. Atomic absorption (AA) spectroscopy is utilized in forensic examinations involving suspected heavy metal poisoning determinations in tissue samples, other biological materials as well as for gunshot residue analyses. Forensic applications covered include: (i) analysis of foods, plants, snow, and tobacco (minor and trace elements in); (ii) trace element patterns in artificial fibers by inductively coupled plasma atomic emission spectroscopy (ICP AES); (iii) use of inductively coupled plasma mass spectrometry (ICPMS) to determine major elements in drugs as well as ICPAES for the determination of contamination elements that could serve as elemental pattern markers in sourcing batch production, manufacturing sites, or other discriminators that might lead to identifying clandestine laboratories; (iv) determination of modes of suspected poisonings often involving the measurement of mercury, arsenic, and so on, in foodstuffs and drugs, as well as the now common use of human hair as substrate; (v) determination and identification of ammunition manufacturers through the measurement of trace elements in bullets and cartridges utilizing ICPMS and ICPAES; (vi) gunshot residue analysis to determine if an individual or an object was in the vicinity of a firearm at the time of its discharge; (vii) metals analysis with ICPAES for the determination of contamination elements that could serve as elemental pattern markers in sourcing batch production, manufacturing sites, or other discriminators that might lead to identifying clandestine laboratories; (viii) discrimination of precious metals and glass manufacturers according to the trace element composition.

Capillary Ion Electrophoresis in Forensic Science. This covers the analyses of highly mobile, low molecular weight ions for the determination of potential antemortem disease states or time intervals between time of death and time of autopsy. This technique is also utilized for the detection and quantification of potassium and lithium ions in biological fluids and tissues collected in clinical and forensic toxicology.

Chiroptical Spectroscopy in Drug Analysis. This technique using polarimetry for characterization of enantiomerically resolved drug compounds is useful in identifying drugs in forensic analysis. This article describes...
circular birefringence, optical rotary dispersion and circular dichromism as used in identifying pharmaceutical diastereomers including alkaloids, terpenes, barbiturates, benzodiazepines, indoloalkaloids, nucleic acids and nucleotides as well as amino acids and peptides and proteins and sugars. Metabolites of these compounds can also be identified.

**DNA Extraction Methods in Forensic Analysis.** The extraction of DNA from scarce or badly degraded substances remains a significant problem and the ability to overcome it remains crucial since the success of all DNA analyses depends on successful initial extraction. Forensic substrates vary from fresh materials with abundant DNA, through putrefied materials also with abundant DNA, to clean materials and dirty materials with scarce DNA such as sperm, saliva, blood stains, nails and feces. Extraction procedures from cell lysis, protein digestion and solubilization of DNA as well as nonaffinity extraction, affinity and commercial methods are all covered.

**Fluorescence in Forensic Science.** This covers the uses of photoluminescence in criminalistics for ultrasensitive latent fingerprint detection, detection of bodily fluids, visualization of fibers and ink discrimination. While the focus of the article is on visualization and imaging, a discussion of basic molecular photoluminescence phenomena and a description of some useful spectroscopic measurements are also presented.

**Ion Mobility Spectrometry in Forensic Science.** The ion mobility spectrometer is a device that is used primarily for the detection, identification and monitoring of trace amounts of gases and vapors. The instruments used are typically small, portable, handheld or even pocket sized and respond within seconds to parts per billion or even parts per trillion level concentrations. Principles of operation, instrument design and sampling as well as sample introduction are presented. Forensic applications for the detection and determination of explosives, illicit drugs and drug abuse, tear gas, arson, chemical warfare, chemical warfare agents and biological materials are discussed.

**Immunoassays in Forensic Toxicology.** This covers enzyme immunoassay (EIA), radioimmunoassay (RIA), fluorescent polarization immunoassay (FPIA), kinetic interaction of microparticles in solution (KIMS), enzyme-linked immunosorbent assay (ELISA) as well as on-site drug testing immunoassays. Sample preparation and matrix factors are described as well as key issues for forensic applications such as detection limits, cut-offs in ranges, cross-reactivities, interfering substances and interpretation of results. Government regulations, quality control, methods development and comparison with other screening procedures are also covered.

**Mass Spectrometry for Forensic Applications.** This covers mass spectrometry for DNA fragment sizing as well as a number of forensic applications including DNA fingerprinting and the determination of STR and single nucleotide polymorphisms as well as mass spectrometry for analysis of DNA samples for contaminants from the environment. The techniques include electrospray and electrospray time-of-flight mass spectrometry.

**Microspectrophotometry in Forensic Science.** This covers the uses of infrared, Raman and ultraviolet (UV) microspectrophotometry, as a combination of optical microscopy and spectrometry, to supply specific information about the composition and structure of forensic materials. Typically, a Fourier transform infrared spectrometer or ultraviolet/visible (UV/VIS) spectrometer is connected online with an optical microscope. In forensic analysis this is used for the identification of very small amounts of fibers, paints, traces of ink or ballpoint ink on a forged document, and so on. Advantages outlined include the ability to analyze picograms or smaller samples, unambiguous identification and photographing of measured areas of samples, the archiving of measured areas and the elimination of the burdensome process of preparing samples prior to analysis. It is also applicable to forensic samples such as single fibers, inks, hair and oils from the clothes of victims. Additional techniques described include fluorescent microspectrometry.

**Nuclear Magnetic Resonance Spectroscopy for the Detection and Quantification of Abused Drugs.** This covers sample preparation, nuclear magnetic resonance experiments and applications in the confirmation of known compounds, identification of unknown compounds, quantification, impurity profiling, optical purity and analysis of body fluids. The determination of a number of drugs is covered, including amphetamines, phencyclidines, fentanyl, opiate alkaloids, cocaine, cannabinoids, ergot, alkaloids, quinazolinones and barbiturates.

**Polymerase Chain Reaction in the Forensic Analysis of DNA.** This covers the polymerase chain reaction (PCR) technologies for amplification of a particular sequence of DNA in forensic science. A description of the technique is provided, followed by coverage of the analysis of PCR product by Amp FLP and STR methods as well as the use of fluorescent PCR primers. Then, the various techniques used in forensic PCR testing are described as a function of chromosome number and gene name (if named).

**Pyrolysis Gas Chromatography in Forensic Science.** This covers the pyrolytic breakdown of organic molecules by the application of heat in the absence of oxygen and the separation and detection of the pyrolysis products by gas chromatography. This technique is used most often in forensic science to help answer the question, “Could samples A and B have originated from a common source?” Pyrolysis methods are described, followed by the experimental parameters and quality control,
with a description of forensic sample types, including, ink, fibers, rubber and plastic, photocopy toners and adhesives.

Scanning Electron Microscopy in Forensic Science. This presents a description of the scanning electron microscope technique including sample preparation and instrumental parameters. Applications covered include forensic testing of paint chips, glass, metallic fragments, explosives and arson residues, hairs and fibers.

X-ray Fluorescence in Forensic Science. This includes a description of elemental analysis, X-ray fluorescence in forensic protocols, conventional X-ray fluorescence spectrometry, electron probe microanalysis, X-ray fluorescence microanalysis and total reflection X-ray fluorescence spectrometry. Applications are described for the forensic analysis of metals, gunshot residues, paint, glass and soil, fibers, plastics and general polymers.

Atomic Spectroscopy for Forensic Applications

Diana M. Grant and Charles A. Peters
FBI Laboratory, Washington, USA

1 Introduction

Forensic science is a discipline that evolved from the interaction between law enforcement and the scientific community. The typical operating budget of laboratory facilities created to support law enforcement is often far below what is necessary for practical modernization. Hence, routine analyses that require low maintenance and can be readily performed with practical experience were quickly instituted as standard procedures in many such laboratories. As an example, atomic absorption (AA) spectroscopy has served the forensic community for over 40 years and continues to work effectively for such diverse applications as gunshot powder residue analysis and toxicological examinations in suspected heavy metal poisoning cases.

These and other traditional forensic applications have also utilized other forms of spectrochemical analysis such as neutron activation. The advantage of the various forms of atomic spectroscopy over these other methods lies in the practical considerations of accessibility and cost as much as in sampling requirements and detection limits. From well established AA methods to the increasing number of forensic applications being developed for laser ablation/inductively coupled plasma mass spectrometry (LA/ICPMS), modern atomic spectroscopy has proven itself to be a compelling and evolving tool in the investigation of forensic evidence.

1 INTRODUCTION

Forensic science may be defined as the application of scientific methods to problems that are addressed in a courtroom setting. Given that the results of an examination have the potential to affect a verdict at trial, the law provides that physical evidence may be examined by both prosecution and defense experts. The size of a forensic specimen can thus present a sampling challenge for analysts, particularly when a requested examination is destructive. Preservation of collected evidence is always a consideration prior to examination. The analyst must ask the question: “Has the evidence been altered since or as a result of its collection?” Another issue that arises is the order in which examinations are performed so as not to preclude subsequent analyses.

Evidentiary samples are generally analyzed for relational value to a suspect, victim, or crime scene. Specimens may readily associate a subject with a crime scene or victim, as with DNA or fingerprints. More often, however, evidence from a victim or crime scene may be used as a circumstantial link to known materials found on a suspect or in his environment.

For this type of specimen, the associative link will be comparative. That is, the relationship between a known and the questioned evidence will be assessed as to the degree of similarity. Whether the association is formed on the basis of color, texture, diameter, physical impressions, or compositional similarities at the elemental level, the forensic examiner’s written opinion will assess the degree of comparability between the submitted known and questioned specimens.

Forensic scientists are often asked to determine which examinations are best suited to the collected evidence in a given case. Dialog between the scientist and the evidence contributor is then necessary to establish what questions are being asked and if answers are reasonably achievable given the limitations of sample size and the laboratory’s analytical capabilities. After all known or available analytical tools are employed to address the question(s) posed to the laboratory, a solid scientific foundation should be established upon which a legal opinion may be rendered. An ideal scenario would allow that any necessary instrumentation would be readily accessible, specimen size would be plentiful, and the condition of the evidence would be pristine.

External contamination and minimal sample size are just two examples of the problems often encountered
with forensic evidence. As with any object in limited supply, preservation of materials deemed to be evidential in nature is often a fundamental consideration in requests for analysis. Thus, an arguably nondestructive method such as instrumental neutron activation analysis (INAA) is quite useful for a wide range of applications in forensic science assays. However, INAA has not been readily available for use by most forensic laboratories. The lack of convenient accessibility, required licensing for use of such facilities, and regulatory waste disposal issues has led to sustained interest in alternative methods of analysis such as atomic spectroscopy.

Atomic spectroscopy has been well documented in forensic examinations involving suspected heavy metal poisoning determinations in tissue samples, other biological materials, and for gunshot residue (GSR) analyses. While INAA has the advantage of multielement capability for solid samples, which preserves the condition of a specimen, AA is more readily accessible, and ultimately cheaper to use and maintain. The merits of both methods were compared in early forensic application papers.

Atomic spectroscopy most routinely involves dissolution of a solid matrix before analysis. Traditional AA utilizes a flame or furnace system to atomize aqueous samples. Later systems that allow for solid sample atomization have improved sensitivity for a variety of matrices. Most recently, plasma technology has grown in popularity due to its efficiency in ionizing an aqueous sample. Modes of detection have also evolved to improve sensitivity for a variety of matrices with these systems. They range from photomultiplier tubes (PMTs) or electrodeless discharge lamps (EDLs) used in conventional AA instruments to the charge transfer devices (CTDs) found in inductively coupled plasma atomic emission spectrometry (ICP-AES) instrumentation. Some ICP-AES instruments still rely on PMT technology for wavelength recording and enhancement. These systems are still quite useful for some applications and can reach comparable detection levels in certain well-defined matrices. Further evolution has produced inductively coupled plasma mass spectrometry (ICPMS) instrumentation, which utilizes either a quadrupole or magnetic sector detection system for mass-to-ionic charge ratio (m/z) determinations.

Limits of detection for these various atomic methods can range from microgram per gram (μg g\(^{-1}\)) to femtogram per gram (fg g\(^{-1}\)) concentrations depending on the analyte of interest and the sample matrix. Many good general reference books have been written about AA spectroscopy, ICP-AES, and ICPMS respectively. However, for a practical introduction to each, Beatty and Kerber, Boss and Fredeen, and Montaser are useful for both beginner and refresher usage.

2 DEVELOPMENT OF ATOMIC SPECTROSCOPY

The notion of coupling a plasma excitation source with a multielement detection system in the mid-1960s ushered in a new generation of workhorse instrumentation for the modern analytical laboratory. Since then, industrial, environmental, and academic laboratories have demonstrated a wide applicability of plasma techniques to trace element studies. Forensic laboratories have also published studies of atomic spectrometry applications. However, as a discipline, forensic science seeks to apply analytical techniques to evidence in a criminal matter for the purpose of weighing the probative value of that evidence. Therefore, only those techniques that have been tested and validated by the scientific community are suitable for presentation in a courtroom. Such methods are thus no longer considered research endeavors as much as they are new applications of established protocols, already discussed extensively in relevant journals.

Moreover, while all of the conventional atomic spectrometry techniques mentioned thus far have become well established in a variety of analytical problem solving arenas, AA spectroscopy is still the most popular of these methods for routine forensic examinations. Examples range from GSR analysis to toxicological assays for the presence of heavy metal poisoning in hair. Therefore, a discussion of atomic spectroscopy techniques in forensic applications should begin with classical AA protocols.

Slavin credits a 1930 publication by Muller and Pringsheim as the initial discussion of AA instrumentation. This paper described the use of AA spectroscopy in the determination of mercury, an element that remains important in current literature. The first articles that addressed the use of AA spectroscopy in forensic applications, however, did not appear until the early 1970s. These articles, which pertained to GSR analysis, represent early examples of the use of modern atomic spectrometers in forensic laboratories. Before this series of articles, GSR literature concentrated almost exclusively on wet chemistry techniques.

Forensic assays have recently focused on the organic nature of evidence. The most current forensic science review article by Brettell and Saferstein illustrates the number of articles that characterize materials by their organic components. This review of forensic science publications also contains a section devoted to trace evidence studies. It is interesting to note that there are no atomic spectrometry articles listed for the surveyed period that encompasses January 1994 to December 1996. However, more than 300 references related to assorted atomic spectrometry applications appear in an April 1994
review published in the *Journal of Analytical Atomic Spectrometry*. Moreover, many of these topics could be readily interpreted as forensic applications.

The publication of this type of research in a more mainstream spectroscopic journal lends strength to the argument that forensic science is simply applied analytical chemistry. That it is performed as a service to the criminal justice system is secondary to its nature as scientific analysis. For this reason, it is vital that forensic scientists also maintain familiarity with mainstream scientific literature, which often contains articles regarding forensic topics.

Several papers that have concentrated on the use of atomic spectroscopy in forensic applications were published in 1985 by Carpenter, in 1993 by Koons, and by Lalchev et al. in 1997. Each article focused on the use of ICPAES for trace element patterns in materials such as glass, brass, bullet lead, and elevated levels of toxic elements in animal tissues. These articles demonstrate the range of materials that can be of forensic interest, a discipline rich in compositional diversity.

In this diverse environment, developing a preparation method best suited for a given sample size and matrix is a prudent approach to any research study. Several journals publish annual reviews to highlight articles that have been published in a given specialty. These sections are generally grouped by application, with separate editions dedicated to general instrumental advances in atomic emission, AA and fluorescence, and atomic mass spectrometry, respectively. Perusal of these types of review issues is a useful and inexpensive means of staying current with new instrumentation. Moreover, journal sections that describe recent applications in environmental, industrial, clinical and biological materials all contain novel sampling discussions that can be useful to forensic analysts regarding these types of materials.

As discussed earlier, there have been numerous forensic applications throughout the development of atomic spectroscopy. The following sections will attempt to discuss these topics in terms of the various analytical methods that have been applied to a given sample type. Some areas will show the evolution of the spectroscopic techniques available for use. Others will demonstrate that “new” is not always improved, depending on a given sample matrix and analyte of interest.

### 3 APPLICATIONS

A 1993 article in the *Fresenius Journal of Analytical Chemistry* by Paudyn and Smith describes a procedure for the analysis of lead-based paint scrapings by ICPAES after microwave assisted digestion. Using aqueous standards and neutron activation analysis (NAA) as a reference technique, results were reported for both major and minor trace elements in several types of paint samples, including automotive spray paint. A low pressure nitric acid–hydrofluoric acid digestion mixture followed by ICPAES yields comparable results to neutron activation data with equivalent relative standard deviations (RSDs) of approximately 5%. For studies that serve to associate the trace elemental compositions of two or more specimens, this level of uncertainty is generally considered to be acceptable. Furthermore, in comparative examinations, which is the basis of most forensic work, it is more critical to develop associative information about each of the known and questioned specimens than to attempt to fully characterize the trace element profile of any one specimen. Therefore, precision errors approximating 5% between replicate trials of a given specimen have been deemed reasonable for this type of analysis.

The article also mentions earlier work using AA and direct current plasma (DCP) spectrometry, which is beneficial to readers who have access to this type of instrumentation. Analytical instrumentation purchasing decisions in forensic laboratories are often based on practical budgeting rather than ideal conditions. As a result AA, particularly flame AA, remains a popular technique. Part of its ubiquity is due to the plethora of experienced technicians who can operate, maintain, and, if necessary, repair such instrumentation.

Virtually everyone with a physical science degree has had exposure to AA in some college course, internship, or employment opportunity. Moreover, procedures for its use with many forensic sample matrices as well as its limitations and interferences are thoroughly documented in textbook literature. Thus, it is widely accepted in the forensic community.

Another reality of forensic work is that specimens are frequently received in less than ideal sample quantities or conditions. While the article by Paudyn and Smith suggests an attractive forensic application, most evidentiary paint specimens are chips rather than scrapings. Moreover, comparison of such a complex matrix would most assuredly require a multielement examination technique such as inductively coupled plasma (ICP) or DCP, rather than the time-consuming single-element capability of the traditional AA equipment found in most forensic laboratories.

It is also interesting to note that forensic applications which appear in mainstream atomic spectrometry journals often cite the lack of available background information for the reported research. A 1998 paper by Zieba-Palus published in *Forensic Science International* describes the study of used motor oils by flame AA as a potential forensic examination. The paper also notes that similar work has been published by two separate groups using electrothermal AA spectroscopy and ICPAES. Both of
the latter techniques would be more desirable alternatives to flame AA. Graphite furnace atomic absorption spectroscopy (GFAAS) has detection limits about two orders of magnitude better than either flame AA or ICPAES. For its part, ICP is much faster at detecting emission signals simultaneously or in rapid sequence. Moreover, the higher temperature of a plasma derived excitation source allows for analysis of refractory metals.

Therefore, since this application could be developed for use with any of the aforementioned techniques, the underlying considerations of adequate sample size and predetermination of what conclusions could be drawn from the resultant data must still be assessed for each situation. For example, one must ask what probative value an oil spot on a suspected carjacker’s clothing would have if he were an automechanic. However, if the victim was a mechanic and the suspect was an office worker who had motor oil on his shirt, then the compositional similarities between the victim’s work environment and the suspect’s stained clothing might prove to be significant corroboration of contact between these two individuals. Often, the circumstances of how transference of trace evidence can occur need to be assessed prior to initiation of a potentially meaningless examination.

3.1 Natural Products

Natural consumer products manufactured and grown for human consumption or use is another popular area of study in atomic spectrometry. The distinction between what constitutes a clinical, environmental, or regulatory application versus one that is forensic often depends on the objectives of a given study. While none of the following publications was written to address forensic issues per se, it is not unreasonable to view these articles as a model for that future use.

An article appearing recently in Today’s Chemist at Work, a journal published by the American Chemical Society, described the role of the United States Customs Service in the analysis of imported foods. Customs, a branch of the US Treasury Department, oversees enforcement of trade and tariff regulations. For several years, this agency has utilized ICPMS for the analysis of the trace element compositions found in various food products. Since these levels will vary depending upon where the product was grown, such data are a good indication of the country of origin.

This information aids Customs in several important commerce and food safety issues. First, the amount of a particular product from a given country is often regulated in accordance with trade agreements. Some countries are further banned from trade with the USA as a result of sanctions. Likewise, tariff rates can vary between countries that import the same commodity. Also, certain foods are not accepted from countries whose products could damage domestic crops or place consumers at risk, due to inherent disease, insect infestation, or pesticides used during their growing. This topic, as a novel example of the diversity of forensic work, was also covered by the Washington Post and was presented by Schwartz, the research chemist who developed the protocol, at the 1998 Winter Conference on Plasma Spectrometry held in Scottsdale, Arizona.

Originally, this work was performed with ICPAES, but has been furthered using ICPMS. Decreased instrument sampling time and improved sensitivity over a mass range comprised of 70 elements has allowed for more specimens to be analyzed in a timely fashion. As a result of the additional elements of interest and increased specimen throughput, better differentiation has been achieved between a larger number of samples. Thus, discrimination by country of origin is possible based upon a statistical modeling of the observed concentration differences between products from various global locales. To date, this work has been applied to imported raw peanuts, garlic, coffee beans, and orange juice.

Other articles have focused on the use of atomic spectrometric techniques for analyses of such diverse matrices as olive oil, plants, wine, milk, snow, and tobacco. Given the current litigious climate surrounding tobacco and its by-products, the ability to differentiate plant origins by trace element concentration levels would seem to be of interest to the legal community.

Similarly, an article in the Indian Journal of Forensic Science makes an argument that trace element composition comparisons between ashed tobacco specimens can be made using copper, cobalt, chromium, and zinc. The article does not mention what type of standards were used. However, use of commercially available plant and leaf reference materials in addition to aqueous solutions would seem to provide adequate calibration and check standards.

Another study that looks promising utilized ICPMS to analyze minor and trace elements in cigarettes and raw tobacco. Aqueous stock standard solutions, traceable to the National Institute of Standards and Technology (NIST, Gaithersburg, MD) were used along with standard reference material (SRM) citrus leaves as a check standard. A total of 30 elements were analyzed, including some of the lanthanides and uranium. Rhodium (Rh) was used as the internal standard. No mention is made regarding selected isotopes or interference corrections, both of which are quite important in interpreting the significance of the findings. Regardless, tobacco crops appear to be a promising area for continued forensic research endeavors.
Trace element patterns in man-made fibers have also been explored as a potential forensic application of ICPAES\(^{87}\). This study focused on inorganic additives in polyester fibers. An earlier article also discussed analysis of trace element distributions in several types of commercially manufactured fibers using activation analysis\(^{88}\). Comparing the two techniques as described in these articles, NAA would appear to be a better alternative for this application given its sensitivity for intact 2-mg fiber samples. However, uncertainties of \(\pm 20\%\) are reported for major elements of interest, such as Ti, Sb, Mg, Cu, V, Al, Cl, and Na.

In the former study, it is difficult to ascertain the success of the ICPAES methodology. Little attention is paid to the use and development of the technique itself. Rather, the focus of the article is the statistical manipulation that may be applied to the volume of data that was collected using ICPAES instrumentation of unknown manufacture and configuration. This article therefore serves to highlight an unfortunate gap between research and practical applications; that is to say, the ability to combine critical procedural details with useful applicative conclusions often remains an unrealized goal in forensic literature. The information gap between the research scientist and the caseworking technician must be lessened if productive studies are to be implemented in real time laboratory settings. This disparity is not exclusive to the forensic community. However, it is a scenario that demands attention within this discipline as it continues to arise in evidence admissibility hearings.

New technology is increasingly being introduced into courtrooms, where it is placed under intense scrutiny. In these Daubert hearings (the result of the Supreme Court’s opinion in Daubert vs Merrell Dow Pharmaceuticals 509 US —, 113 S. Ct 2786), the weight of a technology’s evidentiary merits is evaluated. In this regard, it is often easier to define the contribution of developmental research to the advancement of the larger scientific community than to the smaller populations it attempts to serve.

### 3.2 Drugs of Abuse

Atomic spectrometry is clearly impacting upon one high profile forensic application: the prosecutorial war on illicit drug manufacture and trade. Five separate articles were found in nonforensic journals that detail the interest and capabilities of atomic spectrometric techniques in the analysis of drugs of abuse and their derivatives. As early as 1988, when ICPMS had only been commercially available for approximately 5 years, an article in the *Journal of Chromatography* described its comparative use to ion chromatography for detection of inorganic impurities in organically pure methamphetamine\(^{89}\). This application featured analysis of major elements in the alkali and alkali earth series as well as iodine, barium, lead, and several light transition metals. Conclusions resulting from the work emphasized the inhomogeneity of the methamphetamine crystals studied, which therefore went on to require discrete multiple aliquot sampling per specimen. The article also notes that ICPMS was attractive for its speed, and sensitivity. The inaccessibility of neutron activation beyond government laboratories in the authors’ native Japan was also cited as a reason for exploration of an alternative analytical method. A separate research interest was explored in the same year regarding the use of ICPMS for detection of trace elements in methamphetamine hydrochloride\(^{90}\). Many of the same elements were analyzed with NAA used as a reference method.

More detailed papers using ICPAES and ICPMS separately or in concert for analysis of trace element signature impurities in drugs of abuse appeared in the literature in 1995. In a paper authored by members of the National Forensic Chemistry Center, the United States Food and Drug Administration Laboratory in Cincinnati, Ohio, \(\gamma\)-hydroxybutyrate (GHB) was analyzed by ICPAES for the presence of Ba, Ca, Cd, Fe, K, Mg, Ni, P, Pb, Si, Sr, and Zn\(^{91}\). The results were promising as a starting point for identification of “contamination” elements that could serve as elemental pattern markers in sourcing batch production, manufacturing sites, or other discriminators that might lead to identifying clandestine laboratories.

To date, however, it is unknown to the authors if any of this research has been introduced in court. Recall that the Daubert standard, with its four prongs to determine admissibility – testing, validation, error rate, and general acceptance in the scientific community – now applies to all scientific evidence presented in US federal courts.

Also described in this paper was the analysis of ephedrine hydrochloride via ICPMS. The presence of 14 elements including Na, Al, Mn, Rb, Sr, Ba, and Pt was found to serve as a good discriminator between batches of ephedrine samples. Sodium later showed poor day-to-day reproducibility, although it had originally proved encouraging in same-day production trials. The authors theorized that this discrepancy was attributable to cross-calibration problems between the pulse counting and analog detector modes in the ICPMS instrumentation. Given their respective concentrations, detection of the 14 analytes would likely split evenly between the two detector modes. Thus, this problem is nontrivial to atomic spectroscopists and yet not obvious to inexperienced users of the technique.

Another ICPMS paper from 1995 detailed the analysis of trace elements in heroin\(^{92}\). The approach used for sample comparison resembled the paper described earlier by Schwartz of the US Customs Service, in that the heroin
was analyzed for country of origin comparisons between major producers such as India, Turkey, Iran, Pakistan, Mexico, and Burma. Not surprisingly, Mexican data were quite different from the other countries in the study, which share a common geographical locale. Further, Iranian and Pakistani data were indistinguishable on the dendrogram of all analyzed samples. While this paper is a nice representation of the power of ICPMS for use in multivariate statistical compilations, it is more useful for data processing than method development. Conversely, studies such as Schwartz’s work can be an essential component in comparative analytical research due to its description of the analytical method, equipment, and data interpretation steps.

Further controlled substance research utilized electrothermal vaporization AA spectrometry for the analysis of Ag, Al, Cd, and Mn in cocaine and heroin samples. The charring step was omitted from this research in favor of decreasing the sample pretreatment time. Higher drying temperatures were studied, as were lower temperatures in the presence of chemical matrix modifiers. The beauty of this work from the viewpoint of a bench chemist was its use of instrumentation that may already be standard equipment in most forensic laboratories. However, the challenges of adapting a procedure toward a given set of practical conditions including available instrumentation and software options, sample design, operator experience, and time and budget constraints can represent a potentially lengthy technical and logistical research effort.

A more recent application of ICPMS with regard to analyses of drugs of abuse was introduced at the 1998 Winter Conference on Plasma Spectrometry. It was later described in the September 1998 issue of the Journal of Analytical Atomic Spectrometry. Researchers in Australia have attempted to source the provenance of cannabis crops using LA/ICPMS. Elemental patterns of plants known to be grown in different parts of western Australia were studied in an attempt to characterize plant trace element compositions as a product of the soil environment from which they were harvested. Plant specimens were freeze dried, pressed into disks and ablated for sample introduction into a conventional ICP mass spectrometer. Optimization of the instrumental operating parameters was achieved using glass SRMs commercially available from NIST. It is the author’s conclusion that these data would be quite favorably received by a jury of nonscientists due to the obvious concentration differences that could be observed in plants that were geographically isolated from one another. However, the subtle differences that can occur in plants from similar regions, such as that noted in the data of heroin specimens from Iran and Pakistan previously cited, would require a more thorough interpretation in order for the probative weight of the results to be assessed.

3.3 Suspected Poisonings

The distinction between environmental, clinical, and forensic applications is not easily delineated when discussing cases where poisoning is suspected. The methymercury exposure of hundreds of Iraqi citizens in the early 1970s was attributed to ingestion of grain that had been treated with fungicides that contained mercury. While the circumstances were extremely unfortunate, the intent was not criminal. Similarly, the chronic and acute arsenic poisoning of almost 75 consumers in Singapore of traditional Chinese medicines in 1975 was characterized by researchers as overuse of the product and poor quality assurance testing by the manufacturers. However, the presence of cyanide in Tylenol capsules in the USA in 1982 was attributable to an individual’s willful intent to endanger public safety. Therefore, the results of an environmental offense may often have similar consequences as those of crimes against either specific or nonspecific victims. Chain of custody issues and potentially limited sample availability, then, strengthen the commonality in the analyses used for the respective investigations.

Atomic spectroscopy has long been utilized in biological applications that embody a general forensic description. In one study, silicon, in the form of organosilicon oxide polymers, was analyzed by AA with a hollow graphite tube assemblage. This research was conducted as a result of the use of silicone in breast implants. Similar analyses regarding the chronic effects and environmental impact of heavy metals on populations have also been conducted using emission spectroscopy. Mercury determinations by a variety of atomic techniques have also continued to span a wide series of forensic interests. Moreover, the development of ICPMS has generated tremendous interest in the levels of trace elements in biological matrices. A 1997 paper even compared the potential of ICPMS versus NAA in the multielement analysis of earthworms, as indicators of ecotoxicological assessments and the bioavailability of metals in soil.

Arguably, the greatest contributions that ICPMS has made to spectrometric studies have been in the areas of elemental speciation and isotopic ratios. Specifically, arsenic and mercury speciation studies are of interest to forensic analysts, and these topics have been well documented in recent literature. Lead isotope ratios are of particular interest due to the use of lead in water pipes, paint, gasoline, and pottery. Isotopic ratios of lead are often studied in an attempt to trace the lead back to a specific source for both environmental and
archaeological purposes. If the lead is known to have been mined as a primary resource, rather than recycled from a previous use, these ratios can provide useful information as to the isotopic composition of this lead source. Compiling data from various lead mining sites provides a compositional map that can be compared to the lead specimen under investigation in a given study. (124)

Lead isotope ratios in modern-day goods such as ammunition would be of interest to the forensic community, and has been explored by several researchers. However, bullet lead is not culled from a primary source. Rather, it is mostly harvested from recycled automotive batteries, and therefore is not directly traceable back to its origins. Greater emphasis will be placed on this application in a later section.

One of the most popular biological matrices that has been studied in suspected heavy metal poisoning cases is human head hair. (125–127) This matrix is easier to work with than most biologicals, in terms of sample preparation and analytically detectable element profiles, when analyzed in bulk. Elemental concentrations in hair can be as high as 300 times that of blood specimens, with microgram per gram quantities generally considered as an average baseline concentration. (128) Each cited reference describes what a trace element examination of human hair can reveal regarding the subject’s recent environment. They also offer suggestions for sampling.

Much of the early analytical literature, which detailed potential differences between rate of hair growth in males versus females, elemental deposition along the length of a single hair, and, suspected poisonings, were studied using NAA. (129–134) As with many types of specimens, the ability to analyze several milligrams of a solid for up to 30 elements simultaneously is an attractive feature of NAA, assuming that adequate facilities are available for use.

Analyses of hair have also been routinely performed using AA methods, with detailed studies reporting arsenic levels in hair as indicators of environmental exposure or chronic poisoning. (135–145) Such work was also conducted in the early years of suspected arsenic poisoning cases that were analyzed by the FBI Laboratory. However, the advent of the graphite furnace gave way to the development of a protocol that was instituted in 1994. Using this procedure, individual solid head hair samples were placed directly onto a graphite platform situated inside a hollow graphite tube. A chemical matrix modifier composed of palladium and magnesium nitrate was then instrumentally pipetted onto the hair within the graphite tube. (146) NAA was used as a reference method. This work was of great importance to the laboratory for several reasons. Hair specimens, 5 mm in length, were oriented root-to-tip and segmentally analyzed in order to develop a theoretical modeling of a time line during which the poisoning was thought to have occurred. Bulk analysis of hair specimens can prove to be troublesome when multiple strands are analyzed simultaneously because hair can remain attached to the scalp through several stages of maturation. However, this process allows for a representative sampling of the submitted specimen. Moreover, the solid sampling technique eliminated timely dissolution procedures and inherent contamination risks associated with this sample preparation step. While this method is quite useful for single element determinations, the sensitivity and multielement capabilities of a technique such as ICPMS make it a more attractive alternative when the constituents in a suspected inorganic poisoning case are unknown.

ICP-AES has also been used for bulk analyses of metals in cut head hair. However, the cited study determined concentrations for major (Na, Mg, Ca, and K) and first row transition elements using a sample size of 800 mg. Specimens of this magnitude are a rarity for forensic case submissions. (147) As with other applications, ICPMS has created new and exciting possibilities for the examination of trace elements in hair. At least two papers describe recent exploration into environmental pollution effects on cut, bulk head hair samples using ICPMS. A paper from 1994 gave detailed sample preparation criteria and instrumental parameters. (148) That work featured indium as an internal standard, with emphasis placed on cadmium and lead determinations. Levels of these elements and several others, including arsenic, were monitored in hair as a bioindicator of exposure levels in smokers and nonsmokers. A separate 1998 publication described the method used to monitor levels of metals (As, Cd, Cr, Hg, Mn, Ni, Pb, and Sn) in the hair of children in Spain. (113) An internal standard was not used in the latter study, in which arsenic and mercury analyses were conducted using hydride generation rather than a conventional sample introduction system for ICPMS.

Single strands of hair were analyzed for mercury and thallium using ICPMS in a 1993 article by members of the National Institute for Environmental Studies (NIES) in Japan. (149) Flow injection which requires a small sample volume, typically 50 µL, was used for specimen introduction to the plasma. Each sample was segmented in 3–5 mm increments from proximal to distal ends of a single hair. A human hair certified reference material (NIES CRM No. 5) commercially available from the NIES was similarly studied. Mercury was analyzed in the hair of a healthy male whose baseline mercury content was observed to fluctuate over a period of 6 months while he lived in Japan. The authors attributed these data to an increase in fish intake in a subject who prior to this timeframe had rarely consumed fish as part of his daily diet. Hair from a patient who was known to have been poisoned with thallium was also
analyzed. Specimens were collected 3 weeks after he was hospitalized. Levels of 35μg g⁻¹ were detected in the peak section of the hair sample, with the lowest levels (~3μg g⁻¹) also exceeding predicted normal thallium levels (0.016μg g⁻¹). It was theorized that the patient had been exposed to thallium from as early as 8 months prior to this sampling study, which was conducted 3 weeks before his demise.

In the Spring of 1998, the FBI Laboratory received two suspected arsenic poisoning cases within weeks of one another. The decision was made to develop a protocol for ICPMS in anticipation of eventually using this technique for multielement, heavy metal screening purposes. This course of action proved to be particularly timely when the hair of a cohabitating suspect in one of these cases was later submitted in order to rule out environmental factors, after the victim’s hair was found to contain elevated levels of arsenic. Figure 1 represents data from a typical chronic poisoning event that was calculated to have occurred over the course of 1 year.

The two original submissions were first analyzed by the single solid hair segment protocol developed for GFAAS noted earlier. These analyses did not yield the expected results, based on details submitted by the contributors in each of the two cases. Therefore, ICPMS was attempted on bulk hair segments, with solution AA also performed on the digested samples as a reference method. Aqueous arsenic standard concentrations ranged from expected normal arsenic levels of roughly 0.04 μg g⁻¹ up to 64 μg g⁻¹. Indium (115In) was used as an internal standard.

Two isotopes of chlorine (35Cl, 37Cl) were monitored for comparison to the expected argon chloride (40Ar35Cl) interference on the lone naturally occurring arsenic isotope at mass 75. After repeated analyses with this method and discussions with Wallace (150) of Perkin-Elmer, it is now thought that concerns regarding the introduction of chlorine from the hair matrix are unfounded given that the hair is thoroughly washed and rinsed in alcohol prior to analysis. However, if continued monitoring for chlorine is desired, a better gauge of its presence would be observation of the selenium isotope at mass 77, where 40Ar37Cl would be observed as an interferent. Similarly, selenium at mass 82 should be monitored for comparison to Se-77.

Agreement between the two atomic methods was not as good as expected. Concentrations differed by as much as 10–30% between the GFAAS and ICPMS data. Results derived from the conventional AA procedure were therefore reported, given that this protocol was better defined and validated. Table 1 lists the values obtained for both methods in a representative suspected poisoning case.

Subsequent cases were analyzed as bulk specimens due to a lack of sample. Both the aqueous AA and ICPMS protocols were utilized for these cases as well. The AA data were used as the reported method while development work continues on the ICPMS procedure.

### 3.4 Lead Applications

Using conventional mass spectrometry equipment, lead isotope ratios have been discussed in analytical literature since the mid-1970s. (151, 152) This type of research was first published as applied work in specific fields of study that sought to trace lead based objects back to an original source. An article from 1976 appearing in *Archaeometry* discussed the lead isotope ratios in artists’ lead white pigment. (153) This material is ubiquitous in paint media, but its isotopic ratio information has the potential to aid archaeologists in the characterization and source identification of specific production lots. An earlier

*Approximately 25–50 head hairs in each segment.*
paper from 1975 introduced the concept of analyzing lead ratios in bullets for the same purpose.\(^\text{154}\) Similar studies have been carried out more recently.\(^\text{155–157}\) The original paper by Haney and Gallagher\(^\text{154}\) noted that previous work had been done in this area for archaeological and environmental purposes. However, archaeologists traditionally analyze lead pigment from a time when trade and travel was conducted along specific routes that can be usefully mapped. Also, the production of this material was limited. Neither scenario applies to modern-day manufacturing processes.

Ammunition manufacturers estimate that current production rates yield approximately 9 billion bullets per year. This number does not include lead used for shotshell pellets. Another complication is that the four leading ammunition manufacturers in the USA routinely obtain lead ingots from common distribution sources. Moreover, this lead is not from an original source either. Bullet lead is recycled from sources, such as automotive batteries, which may be doped with manufacturer specified levels of antimony at a smelting facility and then shipped to the respective ammunition producers. Trace element concentrations in the recycled lead are generally not a concern for bullet manufacturers, so long as the majority of the product is properly formed and passes routine quality assurance test firing.

With the exception of increasing automation, bullet manufacturing has not changed significantly since mass production became popular during World War I. Lead ingots are purchased from a recycling facility that smelts the lead into a manufacturer’s specified alloy that may contain up to 3% antimony for hardiness. Each ingot, referred to as a “pig”, weighs about 60 pounds. Pigs are melted in a batch process that allows for a continuous supply of the molten product to be solidified into billets, weighing about 125 pounds each. The billets are then forced through a die of specified diameter to form wire, from which the individual bullets are cut and shaped. The uniqueness of each batch of lead is a result of the continuous addition of ingots and recycled scrap lead back into the primary cauldron or melting pot. A batch is thus determined by the size of a given manufacturer’s final melt.\(^\text{158}\)

The formed bullets are only one component of the finished product known as a cartridge. Once the bullet is placed in a cartridge case that houses a primer cup and gunpowder, the assembled cartridges are packaged in sets that range from 20 to 100 per box. Lot numbers are assigned at the time of cartridge assembly and packaging. Therefore, hundreds of boxes may have the same lot number. Due to the mixing of formed bullets prior to assembly and packaging, a single box has been observed to contain up to 12 unique trace elemental composition groups depending on the manufacturer’s protocol for loading cartridges into lots for distribution.\(^\text{158}\)

Several forensic laboratories have investigated compositional bullet lead analysis in research efforts using ICPMS.\(^\text{159–161}\) However, ICPAES remains the preferred method for this type of examination in the FBI Laboratory’s Materials and Devices Unit, where hundreds of these analyses are performed routinely each year.\(^\text{162}\) The FBI’s standard protocol utilizes seven trace elements to compositionally differentiate between lots of bullet lead: Sb, As, Cu, Bi, Ag, Sn, and Cd. Triplicate samples of each specimen are digested in 20% HNO\(_3\) in an 80 °C oven for 4–5 h. After removal from the oven, most specimens are already a homogeneous solution; however, as a final aid to the digestion process, 10 µL of reagent grade HF (49%) is added prior to analysis. Specimens are run against a calibration curve that includes a 99.99995% lead blank standard.

Three SRMs commercially available from NIST are run in triplicate as check standards against this curve. The described method has been employed for over 10 years in the FBI Laboratory. During that time, recorded values for the stated SRMs have varied within an acceptable margin of relative error from those concentrations listed on the certificates issued by NIST. A reference database is utilized to store this information regarding repeated analyses of the SRMs. It is comprised of compositions that have been recorded using NAA, and three different ICPAES instruments, with quantitative information for Bi, Sn, Ag, and Cd resulting from ICPAES analyses only. Figures 2–4 illustrate the average precision obtained for arsenic, antimony, and copper, respectively, in SRM 2416: Bullet Lead (NIST, Gaithersburg, MD) during 30

![Figure 2](image-url) Average precision obtained for arsenic.
residues left behind from a cartridge’s primer components. Organic residues derived from unburned or partially burned gunpowder are referred to as gunpowder GSR. Both species are associated with the discharge of a firearm. Therefore, GSR analyses are performed in order to determine if an individual or an object was in the vicinity of a firearm at the time of its discharge. Currently, the most common techniques used for this examination are AA spectrometry for bulk analysis of swabbed areas and scanning electron microscopy (SEM) examination of dabbed surfaces for particle analysis.\(^{(38)}\)

The presence of GSR indicates that a weapon was fired. GSR examinations are used to determine if the firearm left behind detectable amounts of inorganic residue on surfaces in the vicinity of the discharge or surfaces with which the firearm was in direct contact sometime after its discharge. The results cannot determine the caliber of the weapon used, nor does it identify the shooter.

Subsequent handling of a discharged weapon would be an example of GSR deposition through surface contact. Assuming normal activity, GSR is not likely to remain in detectable concentrations on a surface 6–8 h after a weapon’s discharge. Common sampling surfaces include objects at a crime scene and the hands or clothing of a person who may have been at the scene at the time of the weapon’s discharge. However, if GSR is not detected, no conclusions may be drawn from this test.\(^{(164)}\)

Research is currently in progress to bring GSR testing back on-line for a limited number of approved cases within the FBI Laboratory. The techniques that will be employed are SEM and ICPMS. The latter technique will serve as a screening process for the proper ratio of three elements that define the presence of residue from a discharged weapon: antimony, barium, and lead. If the ICPMS results are conclusive, particle analysis using SEM will be performed to detect the presence of primer particles.

One of the first GSR test methodologies to be published was the paper by Harrison and Gilroy\(^{(43)}\) in 1959. There are still a handful of new applications in modern day literature despite the controversy surrounding what conclusions may be drawn from the examination.\(^{(165, 166)}\) For example, there is little scientific need to perform a GSR study on a victim who has been shot. Similarly, some 0.22 caliber ammunition does not contain antimony in the primer, which is a reality that the forensic scientist must be aware of in order to properly interpret the data from this test.\(^{(10)}\)

While early publications detailed appropriate wet chemical methods for GSR detection, many subsequent articles were published beginning in the 1970s, which focused on the promise of new or combined techniques for this analysis.\(^{(167–176)}\) Drawbacks to these methods include

NAA’s inability to detect lead and flame AA’s lack of sufficient sensitivity for barium and antimony. However, flameless AA applications were quite promising for the advancement of GSR studies involving all three elements of interest. In 1987, three papers were published that demonstrated the popularity of GSR research by a variety of techniques.\(^{(168–170)}\)

The first paper described a procedure whereby gunpowder stabilizers were analyzed by high-performance liquid chromatography for their organic content followed by GFAAS for the characteristic presence of barium, antimony, and lead. In a typical forensic laboratory, it would seem as if this dual approach could be time-consuming and costly. Moreover, the results were not necessarily more compelling than AA measurements alone, given the extra time involved as weighted against information gained from the double analysis.\(^{(168)}\)

The second paper investigated the use of Auger electron spectroscopy as a substitution technique for energy dispersive X-ray analysis (EDX).\(^{(169)}\) The authors described this alternative as a means of depth profiling the layers of particles of interest. Better lateral resolution and peak differentiation were also cited as advantages over EDX measurements. However, this argument does not seem compelling in light of the number of scanning electron microscopy/energy dispersive X-ray analysis (SEM/EDX) papers that continue to appear in the literature. Comparatively speaking, Auger electron spectroscopy does not decrease the time constraints of the examination, instrumentation costs are higher than for SEM/EDX, and a multitude of problems were quickly associated with the carbon planchet collection stubs when compared to those used for EDX.

The third article that was published in 1987 made an argument for the use of SEM/EDX exclusively for GSR analyses.\(^{(170)}\) The opening paragraph acknowledged that the current method of choice for GSR was a bulk analytical approach in which NAA (for barium and antimony) and AA (for lead) were used in concert. In fact, this procedure was employed by the FBI Laboratory at the time of the publication. The paper argued the merits of defining the morphology of a particle as being consistent with GSR as opposed to using AA to quantitate elements that were readily found in nature. Indeed this rationale has been adopted by many laboratories so that the majority of modern GSR analyses are performed almost exclusively by SEM/EDX.

Extensive studies have been performed in this area by the FBI Laboratory as well. As one of the premiere forensic laboratories in the world, there has never been a lack of funding or research talent to promote innovative scientific advances within the forensic community. Work by the FBI Laboratory in the area of bulk GSR examinations included a published hand-blank study from 1990,\(^{(174)}\) in addition to previous research in 1989 that described the use of flameless AA spectroscopy and ICPAES using an updated swab extraction procedure.\(^{(172)}\) Most recently, a 1998 publication details the protocol under investigation by the FBI for the use of ICPMS as a bulk screening technique prior to the use of SEM/EDX for particle identification.\(^{(166)}\) With proper sample collection, including consideration of the timeframe for sample collection and requisite environmental conditions necessary for a valid analysis, ICPMS screening for the presence of GSR will offer significant time savings in the examination process. If ICPMS results produce cause for further study, SEM/EDX can be employed for verification of the presence of specific GSR particles.

The FBI Laboratory’s ICPMS research protocol for GSR was developed on the basis of years of experiments using flameless AA sample collection, storage and analysis. Early models included publications by Triplett,\(^{(176)}\) Gonzales,\(^{(177)}\) and a study by Vandecasteele et al.\(^{(178)}\) The latter article described elemental concentrations that were found to be present in air samples collected in an indoor shooting range. Such studies provide essential background information as to the levels of GSR that can be exhibited by persons in close proximity to a discharged firearm, even if the individual has not actively engaged in the discharge of a weapon. The 1998 paper by Koons\(^{(166)}\) in the Journal of Forensic Science lists the solutions, method and instrumental conditions employed in this pilot study. GFAAS and ICPAES were used as control methods of analysis for this work with comparable results being realized from all three analytical techniques.

A further interest in the development of this protocol is currently two-fold. There is a desire to characterize other elements associated with specific primers or ammunitions. For example, future work may include the study of strontium in nontoxic primers.

Another publication of merit in the analysis of GSR by a variety of spectrochemical methods was published in 1997 by Meng and Caddy.\(^{(165)}\) As a review article, it is a comprehensive analysis of the history of this examination, with information on the composition of primers and the myriad of techniques available for study of the residues produced. While the discussion leans toward an argument in favor of analysis of the organic components in GSR, it is nonetheless a comprehensive treatment of the many considerations that play a role in this examination.

4 METALS ANALYSIS

4.1 General Applications

Another area of analytical endeavor that has embraced the development and increasing availability of ICPAES
is the metals industry. The ability to monitor and control elemental impurities in industrial alloys has made it possible to discriminate between these objects for forensic purposes as well. Nonhomogeneous leaded brass (copper–zinc alloys) studies were published in 1985. Sample sizes of 10–100 µg were found to be adequate for ICPAES analyses. However, specimens of 20 mg in triplicate were used for a similar study involving common household aluminum foils. This material is of interest to forensic scientists due to its prevalence at crime scenes involving narcotics production or the assemblage of improvised explosive devices. The elements of interest in this initial study were Cu, Fe, Ga, Mg, Mn, Ni, Si, Ti, V, and Zn. Analytical precision was determined to be about 1–2% RSD for most of the studied elements.

Further work on aluminum alloy trace element patterns has been reported using ICPMS and glow discharge mass spectrometry by Feng and Horlick. The ion source for the glow discharge measurements was a substitution of the plasma sample introduction system found on conventional ICPMS instruments. While this approach is still more research oriented than applied, using ICPMS for this examination is noteworthy. Moreover, the article provides good background for scientists interested in pursuing laser ablation studies of solid metal samples. The advantages and disadvantages of sample dissolution ICPMS measurements are described in relation to laser ablation analyses.

Since laser ablation is likely to remain uncommon in forensic laboratories for some time, a 1998 paper by Coedo et al. is helpful for its discussion of boric acid as an aid in fluoride detection in steels via ICPMS. The dissolution involves microwave digestion of the specimens for rare earth analysis using flow injection for sample introduction into the plasma. As has been demonstrated for years by archaeologists using NAA and more recently, ICPAES and ICPMS for trace analysis, the rare earth elements offer exceptionally consistent concentration patterns. For this reason, they have served historically as unblemished geographic markers for sourcing production sites.

A feature of flow injection analysis that may increase interest in the forensic community is the small sample volume needed for analysis. Load volumes are typically of the order of microliter quantities. Moreover, the limited exposure of the sampler and skimmer cones, in the ICPMS instrument, to the highly concentrated salt solutions that typify such matrices improves precision measurements because a steady state signal is readily achieved. As a routine application, the technique developed in this study is relegated to the distant future. However, knowledge of its existence is of benefit to front-line forensic laboratories where new challenges are often encountered.

In a 1993 article, Wynn discussed a dissolution procedure for tin–lead solders using a combination of nitric and hydrochloric acids for detection of both trace and major elements using inductively coupled plasma optical emission spectroscopy. The procedure utilized a 1-g sample size, which was digested by the acid matrix on an open hotplate in about 15 min. Calibration standards were comprised of purified solid tin and lead standards, digested in the acid media for matrix matching purposes. Similarly treated SRMs from NIST were used to verify the standard solution concentrations.

Differences between the obtained ICP results and the NIST certified values averaged about 10%. This work is of particular interest in this forensic laboratory because of the frequently encountered domestic terrorism bombing cases in which solder features in the construction of improvised explosive devices. If signature trace element patterns could be developed to source solder back to a unique origin, this information would serve as a powerful investigative tool.

Scientists at the University of Pretoria published a 1996 article in the Journal of Forensic Science describing the use of ICPAES for the study of trace element compositional differences in mild steel. This material is an iron-based alloy containing manganese and carbon in quantities that are difficult to detect and quantify using other methods. The authors explain that mild steel is quite prevalent as a construction material for storage objects such as safes. A common mode of entry into these structures is to cut through the container with an oxygen–acetylene torch. While X-ray diffraction can distinguish the use of a torch from an abrasive cutting tool via oxidation effects, it is not as sensitive to trace levels of impurities in the steel.

This paper further describes the process whereby ICPAES can be used to relate metallic debris found on a suspect to the cut object at a crime scene. First row transition metals were analyzed in two rods of mild steel as a test case. Four specimen aliquots were assayed from a total drilled sample weight of 180 mg. Specimens were digested in a hydrochloric acid–deionized water (40:30 v/v) matrix. The signal from each analyte of interest was ratioed to the intensity of manganese, as it is the most abundant alloying metal present in mild steel. It was concluded that silicon and aluminum could not be reliably distinguished using this method of analysis; however, chromium, nickel, cadmium, zinc, and copper in cutting debris could be sourced back to the parent sample when expressed relative to the intensity of manganese in the specimen.

4.2 Precious Metals

The use of ICPMS to study natural silver artifacts was reported by Longerich et al. in 1987. An argument
is made for the use of ICPMS as a sensitive analytical tool that yields useful trace element compositional information on small, often nonhomogeneous specimens. Twelve elements were studied via ICPMS with comparison data obtained for cobalt, nickel, copper, and zinc using flame AA spectroscopy. While rare earth elements were not targeted in this study, lanthanum contamination was observed as a result of its ubiquity in the given laboratory environment. Moreover, two silver–argon species (\(^{107}\text{Ag}^{40}\text{Ar}^+\) and \(^{109}\text{Ag}^{40}\text{Ar}^+\)) were identified at masses 147 and 149, respectively. These two isotopes would be of interest if samarium were to be included in the study. The absence of other rare earth elements such as cerium, neodymium, and europium supported the discussed conclusions regarding the observed interfering intensities at masses associated with lanthanum and samarium.

Memory effects were also discussed in this paper. High acid content (0.8 M nitric acid versus 0.2 M) and a high dissolved solids ratio were cited as contributors to this problem. One resolution would be frequent cleaning or replacement of the sampler and skimmer cones that separate the air/vacuum interface between the ionization source and the detector. An alternative for stabilization of the signal prior to analysis would be to introduce a slightly more concentrated solution of a given matrix in order to achieve a steady state layer of solid material on the cone surfaces. This method would apply more specifically to a dedicated instrument or set of sampling and skimmer cones, where such luxuries are available.

Related articles that further develop the concept of ICPMS as a tool for the analysis of precious metals have since been published. High purity metals (cadmium, copper, gallium, and zinc) were analyzed for 30 trace elements using high resolution ICPMS. High resolution ICPMS utilizes a magnetic sector mass spectrometer such as that employed in thermal ionization and spark source mass spectrometry instruments. Conventional ICPMS instrumentation is equipped with a quadrupole mass analyzer. In high resolution ICPMS, a quadrupole is utilized as a mass filter prior to sample introduction to the magnetic sector spectrometer. This configuration can achieve mass resolution of the order of 0.1 of an atomic mass unit for certain elements. Mass discrimination in the presence of overlapping isotopes at this level of detection would serve the forensic community in applications such as compositionally sourcing wires found in lamp cords used to bind a victim, or in improvised detonation devices.

Precious metals such as platinum group elements and gold in geological materials have also been analyzed by ICPMS. As an alternative to conventional fire assay methods, ICMS offers a cleaner and safer sample digestion environment in addition to greater sensitivity in analytical determinations. Detection of phosphorus in high purity iron (steel) specimens has also been reported via electrothermal vaporization ICPMS.

The most recent alternative that has been developed for solution nebulization ICPMS where ultra trace analyses are required is the collision cell. This reaction chamber may be either a quadrupole or hexapole that is placed before the conventional quadrupole detector in an ICPMS instrument. Its purpose is to allow for an inlet whereby a previously chosen gas will be introduced to the transported ions in order to form competing reactions with interferents of the analyte of interest. In this way, determinations such as that for calcium at mass 40 are possible when the potential argon interference is eliminated by its preferential bonding with the reaction gas.

Similarly, the mass filter portion of this chamber sets a window through which only the analyte of interest is able to pass into the conventional quadrupole mass separator under the specified conditions. The obvious first-generation users of such advanced technology would be the semiconductor industry in which high purity acids are required for production use. Environmental and biological uses are also facilitated by the collision cell’s ability to characterize, for example, chlorine, selenium, and lead isotope ratios.

As stated earlier with regard to arsenic in hair analyses, chloride levels are not thought to be a significant analyte interferent for prewashed hair specimens. Therefore, such technology as the collision cell chamber would not be warranted for this examination on a routine basis. Moreover, the instrument design is such that only highly pure solutions may be analyzed in this manner, a requirement that perhaps disregards forensic specimens by definition. However, it is an advancement of note for potential future applications.

5 GLASS

As with metals, glass is a material that has been studied from a multidisciplinary perspective. Its trace element profile is of interest in manufacturing, both from an historical and an industrial perspective. Given the types of glass used to manufacture window panes in homes, offices, and automobiles, as well as, its use for headlamps, flashlights, and costume jewelry, compositional analysis is also of interest in the forensic community. As the manufacturing process is refined and tighter quality control limits are set, refractive index differences continue to diminish between batch lots of container and float glasses. In cases where only small fragments of glass are available for comparative analysis,
trace element patterns become critical for a relational assessment to be made between known and questioned specimens.\(^{197}\)

Early work in this area was carried out in 1970 using NAA to distinguish between glass specimens from vehicles involved in a two-car collision. Based on the NAA results, glass transfer was found to have occurred between the victim’s shattered Jeep windshield and the carriage of the truck that hit it. The truck fled the scene and the Jeep’s driver was killed in the collision. The truck’s driver denied both knowledge of the incident and his truck’s involvement in the accident. However, glass debris found on his vehicle compositionally matched glass specimens collected from the Jeep’s windscreen, indicating that these two vehicles were in contact at some point.\(^{198}\)

Glass analysis was subsequently discussed from the perspective of atomic spectrometry by Hughes et al.\(^{199}\) in 1976. Both flame and furnace AA were used in their research for the determination of manganese and magnesium. These elements were selected as useful discriminators between the following selected glass types: sheet, container, tableware, and headlamp glass specimens. Given the technology that exists today, this procedure would serve as the most basic of elemental screening tests. However, the article does provide useful background information regarding the process of sample discrimination, digestion, and early sample homogeneity results for common glass types.\(^{199}\)

This article was cited and expanded upon by Catterick and Wall\(^{200}\) from the Metropolitan Police Forensic Science Laboratory (MPFSL) in the UK in a 1978 publication that included iron as an element of interest.\(^{200}\) The described digestion was unique in that it substituted the heating of small fragments with a 30-min ultrasonic treatment. A combination of these two practices along with the use of both hydrochloric and hydrofluoric acids is now a generally accepted digestion procedure.

Research into trace element characterization of glass types using ICPAES continued at the MPFSL. As the method was refined and more elements were successfully added to the list of possible discriminators, interest shifted to what conclusions might be based upon trace element patterns in a given class of these specimens. Another scientist at the MPFSL, Hickman,\(^{201}\) discussed the merits of glass classification in a 1983 article.

Hickman worked with archaeologists and long-time neutron activation researchers, Harbottle and Sayre, at Brookhaven National Laboratory in New York, to ascribe meaning to the voluminous data that had been collected to that point. Using ICPAES for Mn, Fe, Mg, Al, Sr, and Ba, NAA for Na, Cs, Sc, La, Ce, Eu, Th, Cr, Se, U, Ca, and Zn, flame emission for K, Rb, and Li, and AA spectroscopy for As, 15 colorless sheet glass samples were analyzed.

ICPAES was further utilized for the study of an additional 232 samples using Mn, Fe, Mg, Al, Sr, and Ba. Sample selection was represented by 10 narrow ranges of refractive index within the range of 1.5150–1.5210. Each of these 10 groups of sheet glass specimens were assessed for the overall discrimination capabilities of this six-element composition assay. The author concluded that the six-element compositional analysis coupled with refractive index measurements was a better discriminator than refractive index alone. However, better analytical precision of the ICPAES technique was needed to further improve discriminating ability between certain regions of refractive index.\(^{201}\)

A 1987 article by the same author furthered this research into the use of multivariate statistical classification for ICPAES glass data.\(^{202}\) An internal standard was added to this study in which both discriminant analysis and cluster analysis were used. Other models such as Bayesian statistics were also discussed as alternative classification methods for this type of sample matrix and analytical method.

Also published in 1987, Koons et al.\(^{203}\) described similar work that was carried out in the FBI Laboratory using pattern recognition with ICPAES for classification and discrimination of sheet and container glasses. A 1991 article further developed the chemical discriminating capabilities available for glass samples with the inclusion of energy dispersive X-ray fluorescence to research involving refractive index and ICPAES.\(^{204}\) These studies have led to the exploration of ICPMS as an analytical tool for glass samples.\(^{205–207}\)

The first article of note in this area was published in 1990.\(^{205}\) It described the dramatic compositional differences that exist between glass specimens from the USA and Australia. Discrimination was defined between two samples as a measure of overlap for any element within a mean confidence of two or three standard deviations. If no such overlap occurred for the elements of interest, the samples were considered to be distinguishable or separate in composition. Such conclusions were based on mean concentrations obtained from five independent samples for both control and suspect glass specimens. Sample sizes as small as 500µg were utilized, with the mean sample size ranging between 800µg and 1200µg. The concentrations of 48 elements were quantified in this study with RSD values of 4% or less.

Fifteen trace elements were identified as discriminators of float glass specimens, such that origin and further subset classification was possible for individual samples. It was concluded that Australian glasses are better characterized by ICPMS than ICPAES when a single technique is preferable, due to the presence of trace elements at nanogram per gram levels in the samples. However,
ICP-AES can accomplish this same task in glasses manufactured in the USA, where trace elements are typically three orders of magnitude more concentrated in the matrix (microgram per gram quantities).\textsuperscript{(205)}

Parouchais et al.\textsuperscript{(206)} supported this conclusion in a 1996 paper in the \textit{Journal of Forensic Sciences}. It was further stated that samples sizes of 100 $\mu$g were necessary to adequately analyze headlamp specimens, while double that amount was needed for container and sheet glass. Using conventional solution nebulization technology, the authors concluded that the minimum sample volume necessary for current ICP-MS instrumentation would be of the order of 2 mL. However, a precision of 1–5\% RSD would require a minimum sample volume of 5 mL for a 1 mg mL\textsuperscript{−1} glass solution.\textsuperscript{(206)} It can often be a difficult task to achieve this sample size in forensic cases. Thus, solid sampling is of great interest, both as a microanalytical technique and for its preservation of specimen integrity. Specifically, the coupling of laser ablation sampling with the sensitivity of ICP-MS detection has generated widespread attention in the pursuit of forensic applications.\textsuperscript{(207)}

6 \textbf{LASER ABLATION}

Ten years after the commercial development and widespread availability of ICP-MS instrumentation, its early proponents were actively seeking the means to expand its versatility. Dissolution requirements of conventional nebulization technology greatly detracted from the appeal of ICP-MS. Therefore, nondestructive solid sampling methodologies were independently pursued in both academia and industry for semiquantitative and quantitative analysis of subpicogram per gram levels of trace elements in inorganic matrices of limited sample size.\textsuperscript{(208–216)} From this work evolved the concept of directly introducing solid material to a plasma ionization source.

Lack of dissolution provides better sensitivity due to the absence of polyatomic species generated by the aqueous medium necessary for conventional nebulization. Specimen size requirements are significantly reduced with solid sampling; therefore, the sampling process can be virtually nondestructive to rare or evidential materials.

Basic explanations of the theory and evolution of laser ablation sampling as related to ICP-MS may be found in these literature references. However, the popularity of the technique has resulted in its discussion in a recent textbook as well.\textsuperscript{(204)} Most commercial systems employ an Nd: YAG laser at a wavelength setting of 1064 nm, which emits a pulsed signal of 500 mJ for sampling purposes. The laser may be rastered across a surface or used for depth penetration studies depending upon the user’s intent.

Sample pretreatment usually involves the removal of surface contamination with the laser system prior to collection of quantitative samples. Determinations of the amount of material ablated with each laser pulse have also been extensively discussed in the literature. Differential weighing is most convenient with adequate weighing apparatus as long as sample positioning is not critical. However, transport efficiency is not factored into this equation and therefore must be assessed using some other criteria, such as internal standardization.\textsuperscript{(217)}

An example of industrial interest in laser ablation was demonstrated when semiconductor companies sought to quantitate the level of actinides in aluminum used to create integrated circuitry. As a quality control issue, this research was given a high priority, so that LA/ICP-MS was aggressively studied and found to be ideally suited for this task.\textsuperscript{(218–221)} For forensic purposes, this research serves as a basis for LA/ICP-MS studies of a variety of metal objects used in the commission of a crime.\textsuperscript{(222)}

Simultaneously, academic researchers became interested in laser ablation as a geochemical sampling tool for the study of minerals. Geological studies by Jarvis and Williams and others serve as good examples of early precious metal applications.\textsuperscript{(223–225)} Subsequent studies of LA/ICP-MS by Watling et al.\textsuperscript{(226)} have yielded trace element characterization of diamonds and their indicator minerals, namely garnets and chromites. From this work and similar research, forensic interest was generated in the prospect of analyzing evidential glass fragments a priori.\textsuperscript{(227–233)}

Early studies discussed the merits of ablating a solid material that had been added to a flux mixture and fused to a glass bead.\textsuperscript{(217)} Particular attention was paid to the use of a matrix element as an internal standard, which is a convenient calibration strategy in homogeneous specimens. The application of this method to the study of rare earth elements in geological materials was further discussed, with detection limits reported in the range of 0.02–3 $\mu$g g\textsuperscript{−1}. The significant reduction of polyatomic interferences as compared to solution nebulization was also noted.\textsuperscript{(217)}

Further interest in the use of LA/ICP-MS for forensic casework has since been generated by the continuation of promising work in this area from researchers at the Chemistry Centre of Western Australia.\textsuperscript{(234)} This group first reported on the use of LA/ICP-MS for trace element determinations in cannabis plants as detailed in an earlier section. That work developed from promising results for similar studies using steel and glass specimens found at crime scenes. These analyses were reported on in the \textit{Journal of Analytical Atomic Spectrometry} in early
1997.\(^{234}\) The laser system used in this work was focused to a spot size of 20 μm with sample sizes of the order of 50 μm in diameter. Sixty-two glass specimens consisting of 31 float glasses, 4 sheet glasses, and 27 container glasses were analyzed. Steel samples were obtained from 69 sources such as safes, firearm barrels, tools, angle iron, rods, and crowbars.

With respect to the glass samples, the authors’ argument against dissolution noted the necessity of hydrofluoric acid in order to digest the silicate matrix. Formation of insoluble rare earth fluorides can greatly affect quantitation of these important fingerprint elements. Thus, the digestion process can be quite lengthy in order to assure removal of excess hydrofluoric acid after the initial matrix breakdown.

According to these authors, the LA/ICPMS process for complex forensic matrices is not yet completely quantitative. However, it is still ideal for these types of specimens because virtually all forensic work is comparative, not absolute in its mission. The question most often asked is: “Do the known and suspect samples match?”, rather than: “What is it?”, or “How much is there?” Thus, for the comparison of small, solid matrices, LA/ICPMS is fast becoming the survey technique of choice.

In the described paper, sample preparation resembled that used for SEM or EDX work, in which the specimen (average size equal to 15 mm in diameter) was embedded in a plastic block of 25 mm diameter and 10 mm thickness. The surface of the block was then polished to expose the specimen. Alternatively, cyanoacrylate was used to embed smaller samples onto the surface of the plastic blocks.\(^{234}\)

The authors further explain that the laser signal optimization was achieved for both sample types using the SRM 610 for Trace Elements in Glass (NIST, Gaithersburg, MD). This particular standard contains a high concentration of the mid-mass rare earth element lanthanum (\(^{139}\)La), which makes it ideal for optimizing both the laser and the ICPMS systems. Further, this glass reference material was used as a standard for both specimens for its production of a clean steady state signal. Continuous ablation with a metal standard could coat the laser cell and contaminate the system over time. It should also be noted that concerns regarding the uniformity of ablation of differing materials which could result in variation of the plasma load function is not at issue in this work because of the comparative nature of the study. Associations between samples of the same type will be based on their relative concentrations, not absolute quantitation of each specimen with respect to a standard or reference material.\(^{234}\)

Lastly, in the Apparatus section of the article by Watling et al.,\(^{234}\) it is stated that the laser can be operated in either the Q-fixed (free running) mode or the Q-switched mode. Steel samples were ablated using the laser in the Q-fixed pulse mode. This setting works well for thermally conducting samples as the energy of the laser radiation is absorbed by the surface, thereby creating deep narrow craters. One to five shots were fired on each site in quick succession rather than over a timed interval.\(^{234}\)

Nonconducting specimens, such as glass, were analyzed using the Q-switched pulse mode, whereby the laser energy generates an ionizing plasma above the focal point on the sample. The authors further explain that sampling is achieved in this mode as the laser-induced plasma couples with the surface of the specimen and cuts into it. Research demonstrated to the authors that analysis of the varying glass types in this study could be achieved with a laser energy of 750 V at a rate of 15 Hz over a 60-s interval.\(^{234}\)

Results of this extensive study demonstrated that reproducibility was readily achieved on a day-to-day basis. Similarly, differentiation was possible on five colorless glass samples with relative refractive index differences of less than 0.1%. Most promising for all aspects of lot production comparisons was the work that demonstrated that brown glass bottles manufactured at the same plant on different days could also be distinguished on the basis of ternary plots of the replicate data. Results for replicate analyses of steel samples showed similar results. Over time, the precision of the analytical technique showed slight variations that in no way compared with the intersample variability demonstrated by repeated sampling of five different specimens of the same type.\(^{234}\)

The development of methodologies such as those demonstrated in this work would obviously require expertise, time, and large specimen banks to begin the evolution of a database for historical comparability. However, once the initial protocols were developed and the software capabilities in place for data storage and access, it is conceivable that training of less skilled or inexperienced technicians for routine use of this technology would be easily achieved. That prospect makes the potential of LA/ICPMS highly promising for routinely analyzed forensic specimens such as bullet lead, glass, steel, copper wire, soils, paints, polymers, and fibers.

The description of each of the techniques mentioned in this article is by no means complete. With regard to forensic applications, the methodologies are not routine in some instances; nor has the need for further exploration of useful methods been exhausted. There will continue to be a need for better detection limits for smaller specimens with less alteration to the integrity of the evidence. As atomic spectrometric techniques become less intrusive through the advent of sample introduction capabilities such as laser ablation, the ability to justify the need...
for such equipment in modern forensic laboratories will become easier. These methods have the advantage of preserving the sample and minimizing the preparation time, both of which are essential criteria for meeting the needs of the criminal justice system.

An inexpensive and continually evolving mechanism for forensic laboratories to stay current with modern trends in atomic spectrometry is through the use of the internet. The July/August 1998 issue of *Today’s Chemist at Work* featured a list of common internet search engine sites that can be used to search for information regarding all aspects of scientific problem solving. Common spectroscopy and spectrometry newsgroups such as *sci.techniques.spectroscopy* and *sci.techniques.mass-spec* were listed, along with World Wide Web sites (Deja News) that do not require individual subscriptions for access. These features, as well as on-line journals and the ease of international communication via e-mail, have increased the forensic community’s ability to stay abreast of research pursuits on a scale that was not previously possible. As a unifying instrument for international communications networking between cooperating forensic and scientific organizations, the internet is developing into one of the most utilized and cost efficient sources of information exchange available to the global forensic community.

**ACKNOWLEDGMENTS**

The authors wish to thank their colleagues in the Elemental Analysis Operations Group of the Materials Analysis Unit for their helpful comments and suggestions. Also, the staff of the Forensic Science Information and Resource Center and the Automation Unit provided immense support, always in a friendly and timely manner.

Electrolyte concentrations can be determined in biological specimens by a number of analytical techniques including flame emission spectrophotometry, atomic absorption spectrometry, high-performance liquid chromatography (HPLC), and potentiometry with an ion-specific electrode. Capillary ion electrophoresis (CIE) is an adaptation of free zone capillary electrophoresis to a particular electrophoretic analysis of highly mobile low-molecular-weight ions.

Vitreous humor electrolyte and nitrogenous compound concentrations are often used to determine potential antemortem disease states or the time interval between time of death and time of autopsy (postmortem interval). Potassium ion concentration in the vitreous humor increases after death, and determination of its concentration in vitreous humor is often used to estimate the postmortem interval.

Lithium ion is considered valuable in the treatment of certain types of mania and major endogenous depression and is even used in the treatment of cluster headaches. The optimum dosage is best determined by monitoring serum lithium concentrations. Lithium toxicity can occur with elevated serum lithium concentrations and repeated measurement every 3 h of serum lithium concentrations is recommended for intoxicated patients to differentiate acute poisoning from chronic toxicity and to determine the best course of therapy.

The development of the CIE methodology reported herein offers a different qualitative and quantitative analytical technique to detect these ions in biological fluids and tissues. Application of CIE analysis for detection and quantitation of potassium and lithium ions in biological fluids and tissues commonly collected and analyzed in clinical and forensic toxicology is described.

1 INTRODUCTION

1.1 History

Electrolyte concentrations can be determined in biological specimens by a number of analytical techniques including flame emission spectrophotometry, atomic absorption spectrometry, high-performance liquid chromatography (HPLC), and potentiometry with an ion-specific electrode. Capillary ion electrophoresis (CIE) is an adaptation of free zone capillary electrophoresis to a particular electrophoretic analysis of highly mobile low-molecular-weight ions.

Vitreous humor electrolyte and nitrogenous compound concentrations are often used to determine potential antemortem disease states or the time interval between time of death and time of autopsy (postmortem interval). Potassium ion concentration in the vitreous humor increases after death, and determination of its concentration in vitreous humor is often used to estimate the postmortem interval. Lithium ion is considered valuable in the treatment of certain types of mania and major endogenous depression and is even used in the treatment of cluster headaches. The optimum dosage is best determined by monitoring serum lithium concentrations. Lithium toxicity can occur with elevated serum lithium concentrations and repeated measurement every 3 h of serum lithium concentrations is recommended for intoxicated patients to differentiate acute poisoning from chronic toxicity and to determine the best course of therapy.

The development of the CIE methodology reported herein offers a different qualitative and quantitative analytical technique to detect these ions in biological fluids and tissues. Application of CIE analysis for detection and quantitation of potassium and lithium ions in biological fluids and tissues commonly collected and analyzed in clinical and forensic toxicology is described.
or postmortem interval.\textsuperscript{13,14} Comparison of the results of vitreous humor analysis to those of other biological specimens such as blood, bile, and urine can be beneficial in determining drug absorption or elimination states, exogenous or endogenous sources of ethanol, pharmacokinetic drug disposition, and diagnosis of diabetes in the deceased.\textsuperscript{14} Vitreous humor electrolyte (sodium, chloride, potassium, calcium, and magnesium) and nitrogenous compound (urea, ammonia, creatinine, amino acids, and xanthine) concentrations are often used to determine potential antemortem disease states or time interval between time of death and time of autopsy (the postmortem interval).\textsuperscript{13}

Potassium ion concentration in the vitreous humor increases after death. This finding was initially reported by Jaffe\textsuperscript{15} and subsequently corroborated by others.\textsuperscript{16–25} The increase in vitreous potassium concentration has been found to correlate to postmortem interval but with greater variation with increased interval. Variation in potassium concentration/interval correlations due to cause of death\textsuperscript{24–26} as well as variability in potassium concentration measurement due to method of analysis has made reliability in vitreous potassium determined postmortem intervals questionable.\textsuperscript{27,28}

Lithium ion is considered valuable in the treatment of certain types of mania and major endogenous depression. It is commonly prescribed by psychiatrists for the treatment of manic-depressive illness\textsuperscript{29} as well as aggressive and self-mutilating behavior.\textsuperscript{30} It is even used in the treatment of cluster headaches.\textsuperscript{31} The mechanisms underlying how lithium works remain largely unknown, although there is strong evidence to suggest that it affects the phosphoinositide second messenger system in the brain.\textsuperscript{32} Lithium is administered orally as a carbonate or a citrate in daily doses of 600–2400 mg. The optimum dosage is best determined by monitoring serum concentrations.\textsuperscript{33} The optimum serum lithium concentrations have been found to range from 0.5 to 1.3 mmol L\textsuperscript{−1} for most patients.\textsuperscript{34} Signs of lithium toxicity include nausea, vomiting, diarrhea, weakness, ataxia, blurred vision, confusion, stupor, seizures, and coma. Lithium toxicity is often seen if serum concentrations exceed 2 mmol L\textsuperscript{−1}. Repeated measurement every 3 h of serum lithium concentrations is recommended for intoxicated patients to differentiate acute poisoning from chronic toxicity and to determine the best course of therapy.\textsuperscript{35,36} Recent reports suggest that rapid removal of pharmacologically excessive lithium concentrations from lithium intoxicated patients, as might occur with hemodialysis, can lead to serious toxic effects.\textsuperscript{37,38} The deleterious effects of rapid lithium removal may in part be similar to what is observed in rats when they are rapidly corrected to normal sodium levels after being hypernatremic.\textsuperscript{39}

The methods described herein\textsuperscript{11,40} were developed to determine the applicability of CIE analysis for detection and quantitation of significant ions in biological fluids and tissues commonly collected and analyzed in clinical and forensic toxicology.

1.2 Theory

CIE is a free zone capillary electrophoresis separation technique for the analysis of low-molecular-weight inorganic and organic ions in aqueous solutions. An aqueous solution of electrolytes is drawn into a hollow silica capillary by hydrostatic sampling and a voltage is applied. Ions migrate toward the electrodes of opposite charge causing the fluid within the capillary to move, defined as electroosmotic flow. An ion’s mobility or migration toward an electrode in an electrolyte solution is directly proportional to the ion’s equivalent ionic conductance, which is related to the ratio of the ion’s net charge to ionic size in solution. Thus the greater the mobility value the faster the ion moves toward the attracting electrode. Differences in ionic mobility results in separation of the ions as they migrate through the capillary. Individual ion mobility and selectivity can be altered in the electrolyte by addition of osmotic flow modifiers (e.g. surfactants and metal–organic complexation) for faster and more reproducible separations.

Indirect ultraviolet (UV) absorption is used to detect the ions as they migrate within the capillary and through the detector. A UV-absorbing electrolyte co-ion is added to the electrolyte solution. The analyte ion will proportionally displace the UV-absorbing electrolyte co-ion producing a decrease in background absorbance which is detected as a peak in the electropherogram. Determination of each ion’s relative migration time is used for identification, and interpolation of the relative peak size for each ion is used for quantitation.

2 SPECIMEN HANDLING

2.1 Blood

Blood was collected from fish via cardiac puncture into microhematocrit tubes (Fisher Scientific Co., Fairlawn, NJ). Plasma was separated by centrifugation in a Model 235C microcentrifuge (Fisher Scientific Co., Fairtown, NJ) at 15 000 \textdegree C until analysis.

2.2 Vitreous Humor

Human vitreous humor was collected by needle puncture of the posterior chamber of both eyes and stored in a sterile Vacutainer® tube. Specimens were stored at 2–4 °C until analysis.
2.3 Other Biological Tissues

Brain and liver specimens from fish were collected at autopsy and stored in plastic sealable bags (Fisher Scientific Co., Fairlawn, NJ). Tissue specimens were stored at −70°C until analysis.

3 MATERIALS AND METHODS

3.1 Reagents

3.1.1 Reagents for Potassium Analysis

Run electrolyte was prepared by placing 100 mL of water (18 MΩ) in a 250 mL flask on a magnetic stirrer. Then 67.7 mg of hydroxyisobutyric acid (HIBA), 64 μL of UV-CAT-1 reagent (containing 4-methylbenzylamine, Waters Corporation, Milford, MA) and 52.8 mg of 18-crown-6-ether (Fisher Scientific Co., Fairlawn, NJ) were added. The solution was stirred to dissolve, and degassed under vacuum. Run electrolyte was prepared fresh daily. An internal standard (40 ppm barium) was prepared by diluting 40 mL of barium (1000 ppm, Fisher Scientific Co., Fairlawn, NJ) to 1 L with water (18 MΩ). Standard solutions of the cations were prepared from 1000 ppm standards of each ion (Fisher Scientific Co., Fairlawn, NJ) as follows: 1000 ppm, 100 μL of each ion quanta satis (qs) 10 mL with 40 ppm barium; 500 ppm, 50 μL of each ion + 200 μL water qs 10 mL with 40 ppm barium; 250 ppm, 25 μL of each ion + 300 μL water qs 10 mL with 40 ppm barium; 100 ppm, 10 μL of each ion + 360 μL water qs 10 mL with 40 ppm barium.

3.1.2 Reagents for Lithium Analysis

Run electrolyte was prepared by placing 100 mL of water (18 MΩ) in a 250 mL flask on a magnetic stirrer. Then 67.7 mg of HIBA, 64 μL of UV-CAT-1 reagent (containing 4-methylbenzylamine, Waters Corporation, Milford, MA) and 52.8 mg of 18-crown-6-ether (Fisher Scientific Co., Fairlawn, NJ) were added. The solution was stirred to dissolve and degassed under vacuum. Run electrolyte was prepared fresh daily.

An internal standard (40 ppm is equivalent to 0.29 mM barium) was prepared by diluting 40 mL of barium (1000 ppm, Fisher Scientific Co., Fairlawn, NJ) to 1 L with water (18 MΩ). A standard 500 ppm solution of the cations (potassium, calcium, sodium, barium, and lithium) was prepared by dilution of 1000 ppm standards of each ion (Fisher Scientific Co., Fairlawn, NJ) with water (18 MΩ).

3.2 Specimen Preparation

3.2.1 Vitreous Potassium Analysis

Vitreous humor specimens were prepared as follows: 1:100 dilution, 100 μL vitreous fluid + 300 μL water qs to 10 mL with 40 ppm barium; 1:500 dilution, 1 mL of 1:100 dilution + 200 μL water qs to 5 mL with 40 ppm barium. Dual dilution is needed to cover the vast range of cation concentration variation in the vitreous humor (sodium is much greater than the other cations). Specimens, standards and controls were all analyzed at 1:100 dilutions in 40 ppm barium. Specimens outside of the range of linearity were diluted 1:500 for quantitation. Aliquots (100 μL) of specimens and controls were transferred to 0.5 mL polypropylene sample vials (Waters Corporation, Milford, MA) and placed in the sample carousel of the Quanta 4000 for analysis.

3.2.2 Lithium Analysis

Ten-μL aliquots of plasma, 10 μL of 0.29 mmol barium in 18 MΩ water and 10 μL of lithium were added to 30 μL of 18 MΩ deionized water and centrifuged in a microcentrifuge (Model 235C, Fisher Scientific Co., Fairlawn, NJ) at 15 000 g until analysis. A standard 500 ppm solution of lithium was prepared by dilution of 1:100 dilutions in 40 ppm barium. Dual dilution is needed to cover the vast range of cation concentration variation in the vitreous humor (sodium is much greater than the other cations). Specimens, standards and controls were all analyzed at 1:100 dilutions in 40 ppm barium. Specimens outside of the range of linearity were diluted 1:500 for quantitation. Aliquots (100 μL) of specimens and controls were transferred to 0.5 mL polypropylene sample vials (Waters Corporation, Milford, MA) and placed in the sample carousel of the Quanta 4000 for analysis.

Liver and brain specimens (300–500 mg) were homogenized 1:4 w/v with 18 MΩ water. Whole tissue homogenates were spun in a microcentrifuge (Model 235C, Fisher Scientific Co., Fairlawn, NJ) at 15000 g in 10 000 nominal molecular weight limit (NMWL) Ultrafree®-MC Centrifugal Filter Unit tubes (Millipore Corporation, Bedford, MA) to remove high-molecular-weight components that might clog the electrophoretic capillary tube. The lithium concentrations were 0.1, 0.25, 0.5, 1.0, 1.5 and 2.0 mmol for development of standard curves or 0.375 and 0.75 mmol to assess within and between-day precision. Final sample assay volumes were 30 μL.

Liver and brain specimens were collected. Ten-μL aliquots of supernate, 10 μL of 0.29 mmol barium in 18 MΩ water and 10 μL of lithium were added to 30 μL of 18 MΩ deionized water and centrifuged at 15 000 g in the Millipore Ultrafree® units. Final sample assay volumes were 30 μL.

3.3 Instrumentation

Samples were analyzed on a Waters Quanta 4000 Capillary Electrophoresis System with a Waters 745 Data Module (Waters Corporation, Milford, MA). Analytical conditions: hydrostatic sampling time, 5 s for plasma and 10 s for vitreous, liver and brain; run time, 7 min at 25°C; power supply, positive 20 kV; autopurge between samples, 1 min with buffer (the capillary is flushed with clean buffer to remove any contaminants); current, approximately 5 μA; detector polarity, negative; UV
detection, 214 nm; absorbance range, 0.02 absorbance units full scale; time constant, 0.3 s. The 745 Data Module settings were as follows: attenuation, 4 mV to full scale deflection; chart speed, 2 cm min⁻¹; peak width, 3; time function now (TFN), peak marker (PM) on; peak threshold (PT) evaluation, run after electrolyte was allowed to stabilize in the capillary for 10 min (value should be between 50 and 200). Dialog for integration was as follows: time, 0.1 min, PT 90 (only if PT evaluation is greater than 90); time 0.2 min, auto zero (AZ) on; time 2.0 min, AZ on; time 7 min, end run (ER) on.

A Waters Accusep Capillary (75 µm x 60 cm) was used for these analyses. Carousel set-up was performed by filtering 17 mL of capillary ion electrolyte through a 0.2 µm Anotop™ 25 inorganic membrane filter (Whatman International, Ltd., Maidstone, England) using a 20 mL syringe (Fisher Scientific Co., Fairlawn, NJ) into each electrolyte reservoir to be used. One reservoir was needed for each group of five samples. The maximum number of samples per carousel was 20. No preconditioning was performed on the capillary, and the run electrolyte was allowed to equilibrate within the capillary for 10 min (as noted above) before analyses were performed. Stabilization produced a steadier baseline and better electropherograms with this procedure and integrator.

3.4 Calculations

3.4.1 Vitreous Potassium Calculations

Cation concentrations were used in ppm to make handling of the solutions easier. Concentrations of each ion were converted into millimoles per liter based on their molecular weight, to be relevant to the forensic and clinical literature. Linear regressions for the standard curves of concentrations and peak area ratios (peak area of analyte: peak area of internal standard) as well as means, standard deviations, and errors were calculated using a model 1860 statistical programmable printing calculator (Monroe, The Calculator Co., Orange, NJ). Specimen concentrations were determined by interpolation of their peak area ratios from those of the standard curves. Coefficients of variation (CV) were determined by dividing the standard deviations by the means and multiplying by 100.

3.4.2 Lithium Calculations

The lithium concentrations used were in millimoles, to make handling of the solutions easier. Concentrations for individual tissue samples were converted into nanograms of Li per milligram of tissue or nanograms of Li per microliter of plasma. Linear regressions for the standard curves of concentrations and lithium: barium peak area ratios as well as means, standard deviations and errors, and CV were determined using Stat View Student Software (Abacus Concepts, Inc., Berkeley, CA) for a Power Macintosh computer (Apple Computer, Cupertino, CA). Specimen concentrations were determined by interpolation of their lithium: barium peak area ratios from those of the standard curves.

3.5 Linearity and Reproducibility

3.5.1 Vitreous Potassium

Standards of each analyte were prepared in deionized water over a concentration range of 100–1000 ppm for determination of linearity. Aliquoted samples of each cation were analyzed to determine within-day (n = 5) and between-day (n = 5) CV.

3.5.2 Lithium

Standards of lithium were prepared in plasma and brain or liver homogenate over a lithium concentration range of 0.1, 0.25, 0.5, 1.0, 1.5, and 2.0 mM for determination of linearity. Control specimens were analyzed at 0.375 and 0.75 mM lithium concentrations. Aliquoted samples of each concentration were analyzed to determine within-day (n = 5) and between-day (n = 5) CV.

4 APPLICATION RESULTS

4.1 Potassium

A typical electropherogram for a 1:100 dilution of a mixture containing 250 ppm standards of all the cations (and barium, internal standard 40 ppm) is illustrated in Figure 1. Migration times were: potassium, 3.24 min; calcium, 3.84 min; sodium, 3.98 min; barium (internal standard), 4.68 min; lithium, 4.79 min. A typical vitreous humor electropherogram is illustrated in Figure 2. As many of the vitreous humor specimens are collected from severely decayed bodies, it is possible for them to contain significant concentrations of ammonia. An electropherogram of an actual specimen illustrating the separation of ammonia from the other cations is presented in Figure 3.

Correlation coefficients (r) between peak area ratios and concentration ranges of 100–1000 ppm for each cation are given in Table 1 (each value is for a between-day analysis). Correlation coefficients ranged from 0.9855 to 0.9999. Both within-day and between-day CV are given in Table 2. CVs ranged from 1.45% to 13.8% between-days and from 1.38% to 9.43% within-day.

Application of this methodology to 25 vitreous humor specimens from forensic autopsies was compared to analysis by ion-specific electrode for potassium concentration. Comparison of CIE to ion-specific electrode analysis
Figure 1 Electropherogram of standard cations (1:100 dilution of 250 ppm each ion in 40 ppm barium): 1 = potassium, 2 = calcium, 3 = sodium, 4 = barium internal standard, 5 = lithium. 4.2 Lithium

A typical electropherogram for a mixture containing 500 ppm standards of cations is illustrated in Figure 5. The migration times were potassium 2.98 min, calcium 3.48 min, sodium 3.60 min, barium 4.15 min, and lithium 4.26 min. Lithium and barium migration times were stable and reproducible (mean relative migration time for lithium/barium from all standards was $1.0184 \pm 0.0011$, $n = 78$). A representative electropherogram of fish liver extract is illustrated in Figure 6. Electropherograms for plasma and brain extract (not shown) were similar. Standard curves of lithium/barium peak area ratios versus lithium concentrations for plasma and for liver and brain of vitreous humor potassium concentrations (Figure 4) revealed a correlation coefficient of 0.9642.

tissue extracts are shown in Figure 7. Equations for linear regression and variances between peak area ratios and concentrations are also shown in Figure 7. Correlation coefficients ranged from 0.976 to 0.996. Both within-day and between-day CVs are given in Table 3. CV values for lithium concentrations ranged from 4.07% to 15.71% between-days and from 4.38% to 7.76% within-day.

Application of CIE lithium methodology to the determination of lithium from plasma and tissues of fish consistently dosed for 23 days is given in Table 4.

5 DISCUSSION AND CONCLUSIONS

5.1 Advantages

The CIE cation separation was obtained with a short, small-bore capillary column with minimal run electrolyte solution (<2 mL per analysis). Barium can be used as an internal standard to improve accuracy and precision.
as well as quality assurance with each analysis. Baseline separation was obtained for the cations of interest in under 5 min. Direct analysis of the vitreous humor (after appropriate dilution to obtain concentrations within the instrument’s sensitivity and analytical range) is a distinct advantage. The aqueous nature of the vitreous humor allows direct analysis without pretreatment or filtration. Analysis of biological specimens with large concentrations of proteins, lipids or other endogenous constituents (i.e. plasma, urine, or tissue homogenates) can be accomplished with easy removal of interfering substances by centrifugal ultrafiltration to allow for determination of electrolyte concentrations in the resulting filtrate solution.

Ion electropherograms are more similar to capillary gas chromatography (CGC) chromatograms than HPLC chromatograms in peak shape and size characteristics. Separation efficiencies are equal or greater than HPLC. The use of short (60 cm) noncoated capillaries which are relatively inexpensive is a distinct advantage versus typical columns used in HPLC. Bulk capillary tubing can be easily cut to the desired length and the optical detection section made by burning the polyamide coating off the fused silica capillary, or standard commercial capillaries can be used. Capillaries of various bore sizes (10–100 µm) can be used which allows for detection of a wide range of analyte concentrations. The CIE methodology described

is automated and as easily operated as any automated HPLC systems encountered by the authors.

The excellent separation capabilities of CIE are demonstrated by the baseline separation of potassium, sodium, barium, lithium, calcium, and ammonia, and by identification and quantitation of multiple ions on each specimen in a single analysis. The hydrostatic sampling (versus electromigratory) and CIE separation produced accurate and precise quantitation. The UV detection at 214 nm (versus 254 nm) offered an adequate minimum detectable concentration and a linear range of detection. As the optical detection cell is within the capillary, the bore size has a directly proportional effect on the limit of detection and the separability of the analytes. The internal diameters most useful are 50–75 µm, as narrower bores clog easily and larger bores result in increased heat production. The limit of detection with biological specimens is not a problem and allows for determination of forensically and clinically relevant cation concentrations.

Recent research developments in run electrolyte make improved analysis attainable. HIBA is used in the run electrolyte as a chelating agent (i.e. electroosmotic flow modifier) to control the flow of buffer through the capillary, improving elution and peak shape. Addition of the 18-crown-6-ether provides separation of ammonia from potassium so that comigration of these cations will not occur causing false quantitation of potassium concentrations, which is of particular importance in analyzing postmortem specimens. Addition of 4-methylbenzylamine to the run electrolyte produces a high background absorbance. Detection of the separated ions is by indirect negative UV absorbance produced by displacement of the background co-ion. Decreased absorbance is directly proportional to the concentration of the ion eluting from the capillary. This addition improves sensitivity of detection, especially at 214 nm.

5.2 Disadvantages

CIE is a more complex methodology than potentiometry with ion-specific electrodes. The analysis time per specimen is distinctly longer due to the serial elution of numerous endogenous analytes in any given biological specimen. Elution of multiple analytes of varying concentrations (and often very high concentrations in biological fluids, i.e. sodium and potassium) can cause capillary overloading resulting in misshaped peaks and peak masking. This may necessitate serial dilution and multiple analysis to identify and quantitate multiple ions in a given specimen. Significant preparation of run electrolyte and instrument set-up are needed for a single analysis or multiple analyses with CIE which would not be necessary for potentiometry with ion-specific electrodes.

The operation of the CIE methodology is more similar to HPLC than to CGC. Fresh daily prepared run electrolytes must be made precisely to achieve good reproducible electropherograms, and be filtered and degassed in order to avoid gas bubble formation within the capillary as it heats up under large potentials. Bubbles can produce noisy baselines and false peaks that interfere in the analyses, especially with low-wavelength UV detection, and can even short out the field and abort the run. Run electrolyte depletion can occur with CIE, which does not occur with HPLC because the mobile phase is homogeneous and is under continuous flow through the column. Electrophoretic flow of ions occurs from one electrode reservoir to the other through the capillary. Repeated analyses with the same reservoirs can therefore result in run electrolyte depletion, which can effect both injection accuracy and analyte separation. Limiting the number of analyses per buffer aliquot to five or less circumvents this problem.

5.3 Potential

The CIE methodology has great potential for the analysis of a number of significant chemicals in forensic
toxicology. Although this article focuses on the analysis of potassium and lithium cations in biological fluids and tissues, CIE with a negative power supply can detect anions such as bromide, chloride, fluoride, nitrite, nitrate, and oxalate as well. Toxicologically significant concentrations of these anions in biological fluids and tissues are easily within the detection capabilities of CIE. Quantitation of toxic concentrations of these anions in forensic specimens to determine toxicity or lethality in clinical and forensic cases, as well as the detection of adulterants (e.g. nitrites, nitrates, and hypochlorite), in forensic urine specimens is the focus of future research with CIE.

Other biological fluids (such as perilymph and endolymph of the ear, cerebrospinal fluid, amniotic fluid, and urine) which are primarily aqueous in nature, like vitreous humor, also have the potential for direct analysis by CIE. CIE analysis of ions in these specimens, especially when the amount of fluid specimen attainable for analysis is minimal (i.e. a few microliters), can be beneficial in both forensic toxicology practice and research. In specimens where large concentrations of proteins, lipids, or other endogenous constituents are present and may interfere with analysis or potentially clog the capillary, such as plasma and tissue homogenates, and particularly with the products of putrefaction in forensic specimens, the combination of centrifugal ultrafiltration and CIE analysis will allow for determination of electrolyte concentrations in the resulting filtrate solution. Further application to the analysis of ions from tissue digests or ashed specimens is possible by CIE. The only limitation is that the chemicals to be analyzed must be soluble in aqueous solution.

ACKNOWLEDGMENTS

The authors wish to acknowledge the assistance and support of Dennis Beaudry of Waters Corporation in conducting these investigations. Travis Harrison’s assistance with original potassium research on vitreous specimens was supported by a Howard Hughes Medical Grant through King College, Bristol, VA. The authors wish to express their appreciation for the collaboration of Ellen Rasch, Paul Monaco, Thomas Creson, Travis Harrison, and William McCormick in conducting the original research.

CHIROPTICAL SPECTROSCOPY IN DRUG ANALYSIS

Chiroptical Spectroscopy in Drug Analysis

Harry G. Brittain
Center for Pharmaceutical Physics, Milford, USA

1 Introduction

Optical spectroscopy is generally concerned with measurements of the interaction of electromagnetic radiation (whose energy lies between 10 and 50 000 cm^{-1}) with isotropic (materials incapable of influencing the polarization state of light) or anisotropic (materials having the ability to affect the polarization properties of transmitted light) compounds. The various effects which are sensitive to the polarization state of radiant energy are ignored during the conduct of ordinary spectroscopy, but can be used to study a wide variety of phenomena for molecules lacking certain types of molecular symmetry.

Molecules for which the mirror images cannot be superimposed are denoted as being dissymmetric, or chiral, and these enantiomer structures are capable of being physically separated from each other. The fundamental requirement for the existence of molecular dissymmetry is that the molecule cannot possess an improper axis of rotation. This rule is often trivialized to state that the molecule in question cannot contain either a center of inversion or a reflection plane. The term dissymmetric should be used rather than asymmetric, since it is possible for a molecule to contain proper axes of rotation and still be capable of existing as nonsuperimposable mirror images.

Chiral molecules interact with electromagnetic radiation in exactly the same fashion as do achiral molecules in that they will exhibit optical absorption, have a characteristic refractive index and can scatter oncoming photons. Dissymmetric compounds will exhibit additional interactions with light whose electric vectors are circularly polarized. For example, the plane of linearly polarized light will undergo an apparent rotation (associated with the circular birefringence of the medium) as it passes through a chiral medium (polarimetry), and the magnitude of this rotation will depend on the wavelength of the light used ORD. Similarly, left- or right-circularly polarized light will be preferentially absorbed within the electronic transitions of a dissymmetric compound CD. General and readable introductions to molecular optical activity have been published by Charney\(^1\) and Nakanishi et al.,\(^2\) and a number of monographs exist which deal with chiroptical issues ranging from the theoretical to the practical.\(^3\)–\(^11\)

The pharmaceutical industry has made considerable use of polarimetry as a fundamental technique for

interest is illustrated through the inclusion of appropriate examples.
the characterization of enantiomerically resolved compounds, primarily owing to the specific requirements of regulatory authorities. The use of ORD and CD spectroscopy has been more along the lines of research studies, but these applications can be very important. CD spectroscopy, for example, is the technique of choice to establish the secondary structure of proteins and peptides.

2 CIRCULAR BIREFRINGENCE (POLARIMETRY)

2.1 Background

The study of molecular optical activity can be considered as beginning with the work of Biot, who demonstrated that the plane of linearly polarized light would be rotated upon passage through an optically active medium. Mitscherlich improved the method of measurement through the use of calcite prisms, and the double-field method of detection was introduced. Since these early developments, much advancement in polarimetry has been made, and a large number of detection schemes are now possible.

The velocity of light \((v)\) passing through a medium is determined by the refractive index \((n)\) of that medium (Equation 1):

\[
v = \frac{c}{n}
\]

where \(c\) is the velocity of light in a vacuum. For an achiral medium, the refractive index will not exhibit a dependence on the sense of the polarization state of the light. When the medium is chiral, however, the refractive index associated with left-circularly polarized light will not equal the refractive index associated with right-circularly polarized light, and the velocities of left- and right-circularly polarized light will differ on passage through a chiral medium. Since linearly polarized light is merely the vector resultant of two in-phase, oppositely signed, circularly polarized components, then the differing velocities of the components produce a phase difference as they pass through the chiral medium. Upon leaving the chiral medium, the components are recombined, and linearly polarized light is obtained whose plane is rotated (relative to the original plane) by an angle equal to half the phase angle difference of the circular components. Charney\(^{(1)}\) has shown that this phase angle difference is given by Equation (2):

\[
\theta = \frac{2\pi b'}{\lambda_0}(n_L - n_R)
\]

where \(\theta\) is the phase difference, \(b'\) is the medium pathlength (in centimeters), \(\lambda_0\) is the vacuum wavelength of the light used and \(n_L\) and \(n_R\) are the refractive indices for left- and right-circularly polarized light, respectively. The quantity \(n_L - n_R\) defines the circular birefringence of the chiral medium, and this quantity is the origin of what is commonly referred to as optical rotation.

2.2 Instrumentation

The experimental measurement of optical rotation is extremely simple. The incident light is collimated and plane-polarized, and then passed through the medium under study. Since the polarization plane of the incident light is fixed, the angle of rotation is defined with respect to this original plane. This is carried out by first determining the orientation of the polarizer and analyzer for which no light can be transmitted (the null position), and then finding the new null position after the medium containing the optically active material is introduced between the prisms. The observed angle of rotation is taken as the difference between the two null angles, and a variety of measurement schemes have been developed to obtain the best experimental results. Those more interested in the experimental measurement of circular birefringence should consult the extensive summary of methodology that has been provided by Heller.\(^{(12)}\)

2.3 Application: Enantiomeric Identity and Enantiomeric Purity

The use of polarimetry data for the definitive probing of chemical problems has been effectively superseded by the use of the spectroscopic techniques yet to be discussed. However, this trend has been resisted somewhat by the pharmaceutical industry, where regulatory agencies normally require measurements of specific rotation as one proof of chiral identity. In fact, the measurement of optical rotation (general test (781)) is the only chiroptical test quoted in the United States Pharmacopeia,\(^{(13)}\) which ensures a continued interest in polarimetry. For example, Chafetz has provided a compilation of the specific rotation values obtained for a very extensive list of steroids.\(^{(14)}\)

In principle, the determination of enantiomeric identity by polarimetry is extremely simple. Knowing the sign of the optical rotation for a given enantiomer of a particular compound enables the enantiomers of that compound to be readily differentiated. For instance, \((R)\)-glyceraldehyde will exhibit positive rotation, whereas \((S)\)-glyceraldehyde exhibits negative optical rotation. The enantiomer present to the largest extent can therefore be readily determined in unknown samples of glyceraldehyde.
Unfortunately, the assignment of enantiomeric identity by polarimetry is filled with difficulties and ambiguities unless the conditions of measurement are exactly specified. For instance, L-asparagine will exhibit negative optical rotation when dissolved in water, but positive rotation in dilute hydrochloric acid.\(^{(15)}\) When compounds contain more than one dissymmetric atom, the sign of the observed optical rotation may not enable one to specify fully the relative configurations of all chiral atoms present. Consequently, unless the measurements are performed on highly defined situations, the determination of enantiomeric identity is best accomplished using a spectroscopic or chromatographic technique.

Polarimetry can be extremely useful, however, in the determination of the enantiomeric purity of a resolved or partially resolved compound. In fact, the commonly misused term optical purity properly relates only to the determination of enantiomeric purity by polarimetry. The term enantiomeric purity itself has no clear definition, and its use differs from investigator to investigator. One term used to define the enantiomer composition is the enantiomer ratio (Equation 3):

\[
ER = \frac{\%[R]}{\%[S]} \tag{3}
\]

where \(\%[R]\) and \(\%[S]\) denote the relative percentages of the two enantiomers. A much more useful term in the enantiomeric excess, defined according to Equation (4):

\[
EE = \frac{[R] - [S]}{[R] + [S]} \tag{4}
\]

where \([R]\) and \([S]\) represent the concentrations of the two enantiomers. The enantiomeric excess is also given by Equation (5):

\[
EE = \%[R] - \%[S] \tag{5}
\]

3 OPTICAL ROTATORY DISPERSION

3.1 Background

In his fundamental studies on tartaric acid, Biot found that the magnitude of observed optical rotation varied with the wavelength of light used for the measurement.\(^{(16)}\) The wavelength dependence was found to be influenced by the nature of the solvent used and by the presence of certain cosolutes, and Biot recognized that such investigations could be used to study the interaction phenomena which existed in fluid solution. Until this time, optical rotatory power had been viewed as an inherent fundamental property of a dissymmetric molecule, whose exact sign and magnitude set that compound apart from all others. These findings naturally sparked intense studies.

Biot’s discovery of the wavelength dependence of optical rotation, and his explanation for the phenomena that he observed, followed earlier observations that the optical rotation exhibited by a quartz plate also varied with wavelength. As a result, the measurement of optical rotation has essentially been a study of ORD since the very beginning.

3.1.1 Ordinary Dispersion

Biot’s earliest quantitative measurements showed that the optical rotation (\(\alpha\)) of quartz varied inversely as the square of the wavelength (\(\lambda\)) used (Equation 6):

\[
\alpha = \frac{A}{\lambda^2} \tag{6}
\]

where the constant of proportionality (\(A\)) is a fundamental property of the dissymmetric molecule. Biot subsequently divided all optically active substances into two classes, one of which obeyed his inverse square law and the other containing those that violated the law. Improvements were later suggested by von Lang,\(^{(17)}\) who added an additional molecular constant (\(B\)) to improve the fit with experimental data (Equation 7):

\[
\alpha = B + \frac{A}{\lambda^2} \tag{7}
\]

Others continued to deduce modifications to the law of inverse squares, but none of these proved to be completely satisfactory.

Investigators quickly became aware that the compounds which violated the inverse square law were those which exhibited light absorption at the wavelength of investigation. The relationship between optical rotatory power and wavelength outside of regions of absorption was expressed by Drude,\(^{(18)}\) who introduced the equation that bears his name:

\[
[\phi] = \frac{K}{\lambda^2 - \lambda_0^2} \tag{8}
\]

where \(K\) is a molecular constant, \([\phi]\) is the total molecular rotation at the given wavelength \(\lambda\) and \(\lambda_0\) is the wavelength of maximum absorbance for the chromophore. The Drude equation works fairly well for many organic compounds over the range of 450–700 nm, since their absorption bands are generally located in the ultraviolet (UV) region of the spectrum.

Lowry has provided an extensive summary of the variation of optical rotation with wavelength, temperature, solvent and concentration for numerous organic liquids.\(^{(19)}\) As an example of ordinary dispersion, data reported for the methyl and ethyl ethers of \(d\)-benzylmethylcarbinol

---

\(\text{Chirophtical Spectroscopy in Drug Analysis}\)
are plotted in Figure 1. The optical rotations of both compounds exhibit the typical dispersion which is characteristic of circular birefringence outside of absorption bands.

### 3.1.2 Anomalous Dispersion

As just discussed, the magnitude of circular birefringence increases with decreasing wavelength. This behavior persists until the light is capable of being absorbed by the chiral substance, whereupon the refractive index exhibits anomalous behavior. The anomalous dispersion observed in ORD spectra arises since the refractive index of a material is the sum of a real and imaginary part (Equation 9):

\[ n = n_0 + ik \]  

where \( n \) is the observed refractive index at some wavelength, \( n_0 \) is the refractive index at infinite wavelength and \( k \) is the absorption coefficient of the substance. It has been amply demonstrated that if \( n_L - n_R \) does not equal zero, then \( k_L - k_R \) will not equal zero either.

### 3.2 Instrumentation

An ORD spectrometer in its simplest form would consist of a manual polarimeter through which light of various wavelengths is passed. One measures the optical rotation at each incident wavelength, and obtains the ORD spectrum by plotting the observed values. In an
early improvement, the incident polarizer was rocked through a small angle by an electric motor at low frequency, the passed light measured by a photoelectric cell and the analyzer rotated until a null position was again achieved. Recording ORD spectrometers have been developed which either use the Faraday effect to obtain both modulation and balance or which use servo-driven analyzers to determine the null position. The calibration of ORD spectrometers is verified using the same standards as used for the calibration of ordinary polarimeters. Those seeking more detailed information regarding ORD instrumentation should consult the book by Djerassi.\(^{(3)}\)

3.3 Application: the Octant Rule and Ketone Chirality

The earliest chiroptical work involving chiral organic molecules was entirely based on ORD methods, since little else was available at the time. One of the largest data sets collected to date concerns the chirality of ketone and aldehyde groups,\(^{(21)}\) which eventually resulted in the deduction of the octant rule.\(^{(22)}\) The octant rule was an attempt to relate the absolute stereochemistry within the immediate environment of the chromophore with the sign and intensity of the ORD Cotton effects.

To apply the octant rule, the ORD within the \(n \to \pi^*\) transition around 300 nm is obtained, and its sign and intensity noted. The rule developed by Djerassi and co-workers states that the three nodal planes of the \(n\)- and \(\pi^*\)-orbitals of the carbonyl group divide the molecular environment into four front octants and four back octants. A group or atom situated in the upper-left or lower-right rear octant (relative to an observer looking at the molecule parallel to the \(C=O\) axis) induces a positive Cotton effect in the \(n \to \pi^*\) band. A negative Cotton effect would be produced by substitution within the upper-right or lower-left back octant. The use of the octant rule is illustrated in Figure 3(a) and (b) for the particular example of a generic 3-hydroxy-3-alkylcyclohexanone.

Although exceptions to the octant rule have been shown, its wide applicability has remained established. The ability to deduce molecular conformations in solution on the basis of ORD spectra data has proven to be extremely valuable to synthetic and physical organic chemists, and enabled investigators of the time to develop their work without requiring the use of more heroic methods.

As an example, one may consider the case of \(trans-10\)-methyl-2-decalone, which has been reported to exhibit a positive Cotton effect.\(^{(23)}\) Placing the molecule in its all-chair conformation and then viewing the molecule along the direction of its \(C=O\) bond enable one to deduce the position of the molecular groups in the various quadrants. The substituents of C-10 (the angular methyl group and C-5) lie in a vertical plane, and are ignored. There are no axial substituents on C-1 and C-3, placing no contributions in the lower-left or lower-right octants. C-4 bears no substituents, hence there is no contribution from the upper-right octant. However, there are three carbon atoms (C-6, C-7 and C-8) in the upper-left octant (which would make a positive contribution to the ORD), leading one to conclude that the overall sign of the Cotton effect would be positive.

4 CIRCULAR DICHROISM

4.1 Background

As just discussed, circular birefringence and ORD are easily interpretable outside regions of electronic absorption, but exhibit anomalous properties within absorption bands. This effect arises since the refractive index also contains a contribution related to molecular absorptivity, as discussed earlier. Not only will the phase angle between the projections of the two circularly polarized components be altered by passage through the chiral medium, but also the amplitudes of these components will be modified by the degree of absorption experienced by each component. This differential absorption of left- and right-circularly polarized light is termed CD, and is given by \(k_L - k_R\).

The effect of one circularly polarized component being more strongly absorbed than the other is that when the projections are recombined after leaving the chiral medium, they no longer produce plane polarized light. Instead, the resulting components describe an ellipse, the major axis of which lies along the angle of rotation. The measure of the eccentricity of the ellipse that results from the differential absorption is termed the ellipticity, \(\psi\). It
is not difficult to show that\(^{(1)}\) (Equation 11)

\[
\psi = \frac{\pi z}{\lambda} (k_L - k_R)
\]

(11)

where \(z\) is the pathlength in centimeters and \(\lambda\) is the wavelength of the light.

### 4.2 Instrumentation

Most instrumentation suitable for measurement of CD is based on the design of Velluz et al.\(^{(5)}\) Linearly polarized light is passed through a dynamic quarter-wave plate, which modulates the beam alternately into left- and right-circularly polarized light. The quarter-wave plate is a piece of isotropic material, which is rendered anisotropic through the external application of stress. The device can be a Pockels cell (in which stress is created in a crystal of ammonium dideuterium phosphate through the application of ac high voltage), or a photoelastic modulator (in which the stress is induced by the piezoelectric effect). The light leaving the cell is detected by a photomultiplier tube, whose current output is converted into voltage and split. One signal consists of an ac signal proportional to the CD, and is due to the differential absorption of one component over the other. This signal is amplified by means of phase-sensitive detection. The other signal is averaged, and is related to the mean light absorption. The ratio of these signals varies linearly as a function of the CD amplitude, and is the recorded signal of interest.

The calibration of CD spectrometers has been approached most often by the use of reference standard materials, with various salts of \(d\)-10-camphorsulfonic acid having received the greatest attention. Highly accurate CD spectra of the free acid,\(^{(24,25)}\) the \(n\)-propylammonium and \(n\)-butylammonium salts,\(^{(26)}\) and the tris(hydroxymethyl)aminomethane salt\(^{(27)}\) have been published, and the relative virtues of each material discussed in detail.

### 4.3 Application: Studies of Compounds of Pharmaceutical Interest

It would be impossible to summarize the utility of CD spectroscopy for the study of molecular stereochemistry, but the cited monographs are sufficient for this purpose.\(^{(1–11)}\) Being a variant of absorption spectroscopy, the technique can be used in exactly the same manner, with the differential absorption following its own analog of Beer’s law. In its simplest application, the CD spectrum of a given compound can be used for diagnostic purposes, as was demonstrated in the identification of morphine, codeine, thebaine and noscapine.\(^{(28)}\) Being proportional to concentration, CD intensities can be used to evaluate the concentration of drug substances in pharmaceutical dosage forms.\(^{(29)}\)

As one example of the use of CD spectroscopy for the characterization of compounds of pharmaceutical interest, the CD of highly purified captopril \(1\)-\([\{(S\}3\text{-mercaptop-2-methylpropionyl}\}-\{(S\}\)-proline\),\(^{(30)}\) the diastereomers having been reported.\(^{(30)}\) The UV absorption spectrum of captopril consists of a single band maximum at 200 nm, while the CD spectrum consists of a single negative peak located at 210 nm. The CD spectrums obtained for captopril and its three diastereomers are illustrated in Figure 4, and can be explained largely in terms of a summation of the chirality of the individual components, \((S\)-proline and \(2S\)-3-mercaptop-2-methylpropionic acid. However, this summation was found to be only approximate since the individual chiralities were found to be enhanced in the diastereomer compounds.

According to Purdie,\(^{(31)}\) natural products that are amenable to CD analysis would include alicyclic compounds (e.g. alkaloids and terpenes), heterocyclic compounds (e.g. barbiturates, diazepams, indole alkaloids, quinolines, nucleic acids and nucleotides), amino acids and peptides, oligopeptides, and proteins and sugars (saccharides and polysaccharides). In addition, the technology may also be used to characterize the many molecules that are the metabolites and/or the naturally occurring condensation products of carbohydrates with the other categories of compounds, such as glucuronides and glycosides of these.
One early application of CD spectroscopy for the characterization of pharmaceutically important compounds concerned studies of aqueous solutions of various morphine alkaloids. Although the most intense optical activity was observed at wavelengths shorter than 230 nm, the CD bands most useful for discrimination among the structural analogs occurred between 240 and 300 nm. Spectra obtained for some analogous compounds containing phenolic groups were found to invert depending on whether the phenol was ionized or not, a feature that was exploited for the analysis of mixtures. Heroin could be identified in real samples, since the CD enabled one to discriminate the chiral substance from its matrix.

CD spectroscopy has been useful in the study of various antibiotics, since many of these contain one or more centers of dissymmetry. In one particular example, the strong optical activity exhibited in the visible region by members of the tetracycline family has been reported. One may readily differentiate between the parent tetracycline and its degradant 4-epitetracycline, and this selectivity has been applied to the analysis of commercial products. Penicillin-V and cephalothin were simultaneously determined in buffered solutions of prepared laboratory mixtures, and penicillin-V was easily measured in various media.

Discrimination between penicillins and cephalosporins is nearly impossible unless the compounds are derivatized prior to the CD analysis. CD spectroscopy was used to evaluate the ability of a large number of different solvents to influence the aggregation state of amphotericin B. Using the relative donor/acceptor tendencies known for each solvent system, the factors leading to self-association were deduced. In the absence of strong electron-pair–solvent interaction, amphotericin B prefers to self-associate into oligomeric species. As illustrated in Figure 5, the CD spectra were extremely sensitive toward the degree of aggregation, and the equilibrium could be shifted to any desired position depending on the exact composition of the solvent medium.

CD spectra for the diastereomeric pairs quinine–quindine and cinchonine–cinchonidine were found to be the necessary mirror images of each other, and the compositions of mixtures of these were determined. Spectra for the pilocarpine–isopilocarpine pair were of such low quality that they could be used only for qualitative distinction. In the same study, CD detection combined with UV detection was used to measure enantiomeric excesses in mixtures of t-hyoscyamine and atropine (i.e. racemic hyoscyamine).

Without question, the largest body of chiroptical work on compounds of pharmaceutical interest has been performed on the steroids. Although these compounds contain multiple centers of dissymmetry and theoretically are amenable to polarimetric study, many present a difficult detection problem owing to the small magnitude of the observed effects. This problem is severe for compounds lacking accessible chromophores. For instance, the only unsaturation in cholesterol is the Δ4-double bond, which exhibits an absorption maximum around 205 nm.

Of course, the presence of a chromophore ordinarily yields strong and useful CD, as was previously discussed for ketone groups that permitted the development of the octant rule. CD spectroscopy has been use to characterize and determine a large number of steroids, such as the Δ4-3-keto steroids and 17-keto and 17-ethynyl compounds. Members of the latter series are normally prepared from their corresponding keto compounds, which then presents an impurity species to detect and
quantitate. CD spectroscopy has proven to be an excellent technique for such work.

One very useful approach to the analysis of mixtures is to enhance the selectivity of the chiroptical method further by measuring spectra of the analyte in two different solvent systems, and to use the spectral differences for quantitative analysis. This technique has been applied to the determination of corticosteroids and Δ4,3-keto steroids in pharmaceutical products. Simple derivatization reactions will also affect the spectra in many ways, often resulting in extra selectivity through shifts in the absorption wavelengths, sign reversals and the appearance or disappearance of Cotton effects. One often obtains sufficient selectivity to permit the analysis of binary mixtures using measurements made at only two wavelengths.

In addition to the examples just discussed, a variety of other pharmaceutically active compounds have been characterized by means of CD spectroscopy, including penicillin, tetracycline, anhydrotetracycline, nicotine, various cannabinoids, various corticosteroids, reserpine, ampicillin, naproxen and various cephalosporins.

Advances in molecular biology can be applied to forensic practice with spectacular success. However, the extraction of DNA from scarce or badly degraded substances remains a significant problem and an ability to overcome it remains crucial because the success of all DNA analyses depend on a successful initial extraction. Extraction methods must solve problems associated with low quantities of DNA, DNA degradation, polymerase chain reaction (PCR) inhibitors and failure to solubilize or separate DNA from the substrate. These problems are compounded by the relative lack of knowledge concerning DNA degradation in different forensic environments.

The extraction method must be suitable for the starting material. Fresh material with abundant DNA, such as blood, soft tissue, or saliva, presents no difficulties and DNA suitable for PCR analysis can be extracted easily. In mixed substrates, for instance vaginal swabs from rape victims, male and female DNA can be separated by differential lysis procedures. Putrefied material with abundant DNA, such as blood, soft tissues, and entomological and botanical material, has plenty of DNA, but PCR inhibitors may be present and extraction methods must be chosen that select DNA but not the inhibitors. Clean material with scarce DNA, such as stains (blood, saliva, sperm), swabs (vaginal and from bite marks, fingernails and stains on bodies), fingernails, hair, desquamated cells (skin, dandruff), and certain body liquids (urine, plasma), has a paucity of cellular material and hence low quantities of DNA. The prerequisite here is to reduce the loss of DNA, for example by introducing more specific methods of extraction and reducing the number of steps in the procedure. In the case of dirty material with scarce DNA, such as sperm, saliva and blood stains, nails and feces, not only are there low quantities of DNA, but there are also large amounts of organic and inorganic contamination. The problems faced by any extraction method are to recuperate small quantities of DNA as well as eliminating inhibitors of PCR. Formalin-fixed and paraffin-embedded tissues and stained smears on slides present particular problems associated with damage to DNA due to the processing of the materials. Nevertheless, DNA can be successfully extracted from these substrates. The greatest challenge in forensic DNA analysis is extraction from calcified tissues (bone and teeth). These substrates have obviously undergone considerable degradation and are often contaminated with soil. In addition, DNA undergoes binding interactions with the hydroxyapatite matrix which chemically stabilizes DNA; this aids its survival, but makes it difficult to extract. An essential part of the extraction process is therefore to release DNA from this binding.

Before DNA can be isolated from a substrate, several important steps must be taken. These involve lysing the cells to release the DNA and digesting protein so that as much DNA as possible is solubilized. Many (if not most) techniques – and there are many variations – involve the use of proteinase K (PK) to digest protein and a detergent (often sodium dodecyl sulfate (SDS)) to lyse the cell membranes. The extraction procedures themselves can be divided into two categories: nonaffinity methods where all extraneous material is removed leaving DNA in solution, and affinity methods whereby the DNA is targeted directly and removed from the solution. Each category has many variations and on occasions they can be combined. The
main nonaffinity techniques are phenol/chloroform, salt precipitation and chelex. The phenol/chloroform method is the best known and has an excellent forensic record; it is based on removing protein, thus purifying the nucleic acids which are extracted in aqueous solution; the disadvantages are that it does not remove nonprotein contaminants, several steps are involved in the procedure, and the reagents are toxic. The salt precipitation method is based on salting-out by dehydration and precipitation with a saturated salt solution. It is an excellent method when abundant clean samples are available and is quicker, cheaper and less toxic than the phenol/chloroform procedure. The disadvantages are that it does not eliminate all PCR inhibitors and considerable amounts of protein may be retained. With chelation (e.g. chelex), the active reagent binds to inorganic substances and clears the extract of certain PCR inhibitors, particularly metal ions; an alkaline pH disrupts cell membranes leaving DNA in solution. The method is simple, rapid and does not involve multiple tube transfers, though it does not have a particularly selective action on protein. The novelty of affinity methods is that they actively select DNA by either specific or nonspecific reactions. The main nonspecific affinity method is the glass–milk or silica gel procedure. Very small glass beads are combined with isothiocyanate which itself is bound to guanidium. The positively charged amine groups on the guanidium link with the negatively charged phosphate groups on DNA. Once bound to the glass beads, the DNA can be repeatedly washed and cleansed of all other material before being eluted and subjected to PCR analysis. This is currently the method of choice for difficult substrates; the disadvantage is that when a great deal of contaminant is present, it might sterically hinder the adsorption process of DNA on to the glass substrate. The only specific affinity method yet published uses a murine anti-dsDNA monoclonal antibody of IgG2A subclass bound to paramagnetic beads via anti-murine IgG. The antibody-coated beads react specifically with DNA and can easily be washed free of contaminants. The method is extremely specific and sensitive, positive PCR results being obtainable from as little as 0.005 ng per microliter of DNA. In addition, the bead–anti-DNA–DNA complex can be put directly into the PCR. As yet this method has not been fully tested on all forensic substrates, but initial results are very promising. Commercial DNA extraction kits, for example Dynal DNA direct™, QIAamp®, Prep-A-Gene® and Scotlab GeneClean®, are becoming increasingly available and some provide protocols for forensic substrates. Most of these kits are based on an affinity mechanism. In practice they seem to give reliable results.

In conclusion, DNA extraction methods in forensic analysis seem to be going two ways. For substrates with fresh abundant DNA, extraction presents no problems and any method would suffice; it would seem logical to choose one that uses nontoxic reagents and is inexpensive. The most interesting evolution in extraction techniques is with those dealing with difficult substrates where DNA is scarce or tightly bound and non-DNA contamination is abundant. Recent work suggests that the future in these situations lies with affinity methods and the development of immunoaffinity seems to point the way for future research. Such studies should be combined with investigations into the interaction between DNA and forensic environments so that extraction procedures can be devised for particular circumstances, for only with proper extraction procedures will subsequent DNA analysis be successful.

1 INTRODUCTION: PROBLEMS CONCERNING THE EXTRACTION OF DNA

In spite of recent advances in molecular biology, particularly in the field of forensic sciences (which include the advent of PCR, sequencing, and the plethora of microsatellites and other length polymorphisms used for identification purposes), the extraction of DNA, especially from substrates which may be scarce or badly degraded (for example, dry bone and teeth, old blood stains and hair shafts), still remains a problem.

The possibilities offered by modern-day technology would seem highly applicable to the forensic world, as with specific PCR techniques such as nested PCR, it is possible to isolate typable DNA from a single cell. A single cell contains approximately 10 pg of DNA (i.e. 10 000–100 000-fold less than required for restriction fragment length polymorphism (RFLP) analysis and 100–1000-fold less than for standard PCR techniques), but over 40 cycles of nested PCR will produce a signal visible by ethidium bromide staining of polyacrylamide gel.(1) However, success in practice is greatly different from theory, and methods that allow extraction of adequate amounts of relatively pure DNA from qualitatively or quantitatively scarce material are crucial for the success of all subsequent analyses.

It is frequently reported in the forensic literature that DNA is a fairly robust molecule and that relatively short sequences can survive under appropriate conditions. However, common experience teaches us that with particularly difficult substrates, DNA extraction and/or amplification is often unsuccessful. The main reasons for failure are DNA degradation, PCR inhibition, and failure to solubilize and separate DNA from the substrate of origin. Unfortunately, as often happens among differing scientific disciplines, forensic scientists rarely share or acquire information that originates from other branches of molecular biology. For this reason, valuable
information on diagenesis (the study of the biochemical alterations that biomolecules go through after cell or organism death) which come from the fields of chemistry and geochemistry, may be lost. It therefore seems mandatory to approach briefly the problems behind DNA extraction – or rather the risks of failure to extract informative DNA – before addressing the actual methods themselves. For this reason, it is necessary to understand what little is known about DNA’s behavior, its degradation, and its interaction with other molecules.

Various theories and opinions, more or less corroborated by valid practical results, exist on the survival and behavior of DNA. DNA has been reported as surviving and having been successfully extracted even from historical and archaeological material. The remains of the Romanovs who died in 1918 were identified by DNA analysis. Several authors have identified sex and other informative genetic material from archaeological bone. None the less, it must be stressed that these findings are exceptional, and other experts feel that nucleic acids are amongst the most unstable molecules, and that DNA is likely to survive only in protected settings. This may be the result of its interaction with protective substances surrounding it, for example after having been conglomerated with resistant macromolecules, being bound to other molecules, or encased by crystals. An example is hydroxyapatite crystals in the case of bone. DNA is chemically unstable because of various phenomena such as hydrolysis, oxidation, and nonenzymatic methylation. The cellular destruction that occurs soon after cell death exposes DNA molecules to enzymes and other reagents that cause breakage and further chemical alterations. In addition, environmental agents such as heat, radiation, and microbial attack take their toll. Recent diagenesis studies seem to show that hydrolytic scission events may be crucial to DNA loss, even though the molecule may survive autolytic and biological degradation. Even when it survives, DNA may not be in a PCR-amplifiable form. The lability of DNA and its susceptibility to harsh exogenous and endogenous agents should therefore caution against extreme optimism for the survival of informative DNA in old material. These factors also suggest adopting extraction methods that are not harsh, that avoid further loss of whatever useful DNA may remain, and are chemically suited to the substrate.

Another problem in obtaining a good yield of DNA suitable for PCR analysis is the presence of non-DNA contaminants that may inhibit the PCR. The main contaminant is usually protein and many methods of extraction use phenol because this targets proteins, eliminating them from the DNA solution. However, contaminants of a different nature exist, such as hemoglobin and minerals, which may also act as inhibitors of the PCR. Specific methods of extraction must therefore be used in these cases if inhibition is to be avoided. For example, a copurified hemoglobin derivative (hematin) is postulated to be a major contaminant, and its inhibitory effect can be countered by adding bovine serum albumin to the extract, or by using ultrafiltration, chelating resin treatment, gel filtration, or anion exchange column chromatography. The presence of inhibitors should always be suspected and tested for when a PCR has given an unexpected negative result, by simply adding the extract in different dilutions to known positive controls and verifying whether inhibition occurs.

Perhaps the most difficult problem to solve is the actual detachment of DNA from the substrate. Some materials, for example bone, provide excellent protection of DNA as a result of their crystalline structure on to which DNA seems to adsorb; however, for the same reason it is equally difficult to solubilize DNA from the bone crystals. Any extraction methods therefore need to be adequate to overcome the chemical bonds between DNA and bone without destroying the nucleic acids.

The difficulty in devising such specific methods is that very little is known about the chemical behavior of DNA, even in vitro, although it seems to have been the most studied molecule since the late 1950s. It appears that a variety of structurally diverse low-molecular-weight ligands react with DNA, mainly by noncovalent associations with the minor groove of DNA, intercalation between DNA base pairs, and by alkylation of the component nucleotides. In spite of the innumerable methods used for studying DNA interactions (such as X-ray crystallography and computational modeling methods), its mode of interacting with small molecules or even with macromolecular complexes (such as proteins) remains unknown. Certain molecules, such as water, seem to affect interactions of DNA with other molecules, but the exact modalities, even of this simple reaction, remain unknown. For these reasons, it is all the more difficult to devise adequate extraction techniques for forensic scenarios.

DNA contamination should be briefly mentioned. The extracted DNA may be contaminated by exogenous DNA, which may belong to the person who collected the sample, or extracted it, or may derive from pipets or other laboratory hardware that have been contaminated by other DNA samples, or may be present in aerosol from the laboratory atmosphere. DNA contamination presents one of the greatest risks of PCR analysis because it may lead to dangerous exclusions or false conclusions. To overcome this problem, numerous cautionary measures are recommended and taken by most laboratories working with DNA. These include appropriate washing and sterilization of crushing devices and other tools (with anti-DNA reagents and/or ultraviolet (UV) light), the use of positive displacement pipets, and the testing of
positive and negative control samples with each series of extractions. Also, mock extractions should be carried out in parallel with the specific extraction method being used. For example, nonhuman substrate should be tested (when working with human material), as well as complete blank controls, i.e. distilled water and reagents on their own as in the case of affinity methods, silica powder, or magnetic beads. Contamination risks come not only from the laboratory but also from the forensic site itself, such as the room or area in general where a crime has been committed, where a body has been found, or even the autopsy room. Interestingly, a recent study performed in the New York City Medical Examiner facilities showed that there were moderate quantities of typable DNA contamination, not only in the autopsy room, but also in adjacent room hoods and air vents. However, DNA contamination from airborne sources was not evident. These authors concluded that there should be no contamination of specimens so long as samples were collected into clean containers and not placed directly in contact with contaminated surfaces.\(^{(14)}\)

In conclusion, provided that DNA has survived in a suitable form for PCR analysis in substrates such as old blood stains, dry bone, and hair shafts, then one must make sure the extraction technique chosen will avoid exogenous contamination, eliminate possible PCR inhibitors and release DNA from the substrate. Different substrates react with DNA in different manners and the extraction method must be chemically and physically tailored to the specific kind of substrate. It should be remembered that this is a rapidly growing field, and as more understanding of interrelationships between DNA and other molecules develop, the techniques for extraction will change. This article therefore gives guidance to those methods the authors feel to be most popular and recommendable at the present moment.

2 POSSIBLE FORENSIC SUBSTRATES FOR DNA ANALYSIS, THEIR PECULIARITIES AND PREPARATION FOR EXTRACTION

The extraction method must be suitable for the starting material or substrate on which the analysis is to be performed, different methods being appropriate to different situations. The following briefly lists the major forensic substrates and their peculiarities for DNA extraction. Not all samples need to be treated in the same manner and many different ways of collecting, treating, or preparing the sample prior to extraction have been recommended. This section includes general considerations of these methods.

2.1 Fresh Materials with Abundant DNA

These substrates, which include blood, soft tissue, and saliva, usually give no problems and contain abundant cellular material from which DNA can be extracted by standard methods. They are the substrates on which most of the methods described in section 3 were devised and tested. Fresh blood, soft tissue, and saliva contain a sufficient quantity of well-preserved blood, parenchymal cells and epithelial cells, respectively, for successful DNA extraction. Some soft tissues are preferable, favorites being cervical lymph nodes and muscle.

Fresh blood is perhaps the easiest substrate to deal with. Depending on the method employed, white cells are usually isolated as a buffy coat and DNA extracted from this or, more simply, a few drops of whole blood are used. The need for fresh blood to be extracted in forensic cases is usually related to samples taken from living persons in paternity cases or from suspected perpetrators of a crime who have left organic residues at the scene or on a body.

Relatively fresh samples from soft tissues excised with a sterile scalpel from fresh cadavers must be homogenized in a mill, taking care to thoroughly sterilize the equipment in between the preparation of different specimens. When sampling from a cadaver, muscle and lymph nodes are optimal substrates. About one cubic centimeter of tissue is usually sufficient for several tests.

Blood, fresh tissues and saliva should be stored at \(-20^\circ C\) and homogenized only when needed.

2.2 Putrefied Materials with Abundant DNA

Typical examples of these materials are blood, soft tissues, and entomological and botanical material. These substrates present with putrefied, lysed cells, fatty putrefaction products and/or fibrous organic tissue (the last two are particularly associated with maggots and plants) which tend to inhibit PCR analysis, though not much is known about the mechanism of such inhibition. Although large amounts of DNA are still available, great care must be taken to eliminate PCR inhibitors.

Putrefied blood and substrates containing putrefied blood, in particular, quickly decay, producing hematin and porphyrins which are severe inhibitors of the PCR. In the case of cadavers, blood tends to clot soon after death, entrapping cellular elements and leaving behind few cells actually available for DNA extraction in the fluid component.\(^{(15)}\) Extraction priorities with such abundant, but difficult, substrates must therefore be to discard debris (proteins, lipids, metals) in order to quantitatively and qualitatively eliminate inhibitors and then actively select the DNA. Putrefied soft tissues are extracted for DNA largely in cases of identification of decomposed human remains.
DNA typing of maggots found on cadavers is required to aid in determining time and place of death. Different insect species proliferate at different temperatures, with different velocities and in different environments. At times there may be difficulties in diagnosing the species of a maggot by morphological means alone, so genetic typing must be performed. In the case of plants, toxicological diagnoses may require genetic analysis, as in circumstances where there is a need for diagnosing the species with accuracy, for example Cannabis sativa from a pack of drugs. In all cases of entomological and botanical material the sample is simply crushed to a pulp or to a fine powder and extracted. Fibrous material needs to be eliminated in botanical samples. Maggots have a particularly high fat content, so great care must be taken to remove this component, for example with solvents.

2.3 Clean Material with Scarce DNA

These materials include stains (blood, saliva, sperm), swabs (vaginal, from bitemarks, from fingernails, from stains on bodies or other surfaces), fingernails, hair, desquamated cells (skin, dandruff), and other body liquids (urine, plasma). The main problem with these substrates is the paucity of typable DNA (if indeed there is any at all), because of degradation related to environmental phenomena and time and/or because of the small number of cells involved. In many instances, these substrates are relatively clean from inorganic debris. An essential prerequisite for the method of extraction is therefore to reduce loss of DNA to a minimum, for example by introducing more specific methods aimed at the small quantities of DNA present and reducing the number of steps in the process.

Blood stains can be found on many types of substrates (cotton, denim, carpet, wall board, envelopes, cigarette butts) and DNA is routinely and successfully extracted from all of them. Special care should be taken in these cases to eliminate the hematin and porphyrin components that inhibit PCR. Similar problems arise with fingernails of a victim, which may contain blood belonging to an aggressor.

Most authorities believe that shredding (or cutting into small pieces) fabric or fingernails, prior to elution is the method of choice. Others prefer to elute any residues off the nails, stains or other substrates by simply incubating the entire sample in extracting solution. Time and temperature of incubation may also be important, especially for blood stains because blood seems to be tightly bound to some substrates. In this case, incubation prior to extraction in a buffer at 56°C for long periods (e.g. overnight) may be useful.

In the case of stains (from semen, blood, saliva, sweat, nasal secretions) on fabric, the stain is cut with sterile scissors. The same is valid for fingernails, which can be cut from the cadaver or from a live victim of an attack where there was a fight during which the victim possibly scratched the assailant. The main aim in extracting DNA from any kind of substrate is to expose the maximum amount of surface area of the stain to the extracting agents (most preparations of tissues and other substrates for these purposes involve reduction to small pieces or pulverization).

Nails can also be boiled for 5 min in sterile water prior to chopping as this apparently helps digestion. Nail scrapings or debris should be recovered by swabbing all nails of a hand with a single cotton swab moistened with sterile water.

Similarly, if blood or other body liquids are on the skin, they can be transferred on to a damp sterile cotton swab by swabbing the area in a circular motion for about 30 s. The swab is then dried in the open air for 6 h or immediately frozen at −20°C. The same is valid for vaginal, anal, and buccal swabs for dead or living presumed victims of rape or sexual violence. These are collected by repeatedly swabbing the vagina (in some cases different swabs are taken for external genitalia, vaginal wall and cervix), anus and mouth.

Vaginal swabs in victims of rape are a special case where the presence of genetic material in mixed substrates originating from more than one individual is a frequent problem. The vaginal swabs may contain female epithelial cells and equal amounts of sperm cells. In these instances, where the substrate is relatively abundant, physical separation of the genotypes by differential lysis methods is usually feasible. This involves separating the female epithelial cell fraction from the male sperm cells by using different buffers (section 3). Problems arise with such mixed substrates when the sperm cell fraction is small or when material from victim and aggressor are of the same cell type, for example when the perpetrator’s skin/blood is under the victim’s fingernails. In such cases, allele-specific amplification systems have been devised that allow the detection of individual alleles in a sample with mixed genotype.

Saliva stains can also be useful for analysis, and genomic DNA has been isolated from saliva found on a variety of substrates, such as chewing gum, cigarette butts, and postage stamps. A greater problem arises with saliva left on human skin (transferred by biting, kissing, sucking, licking). In these cases, saliva is usually collected by a different swabbing technique from that described previously for other stains, i.e. the double-swab technique. The affected skin area is swabbed with a dry swab first, then with one previously moistened in sterile filtered distilled water.

Desquamated cells (e.g. from fingerprints or dandruff) are another possible substrate for DNA typing. Contact of
a suspect’s hand, for example fingertips, with household objects, body parts as well as lesions on body parts such as bruises, can leave desquamated epithelial cells which can be collected and typed.\textsuperscript{19} The print only needs to be swabbed, as described above, after having adequately searched and tested the body for fingerprints. For similar reasons, certain objects that have been worn may be proper substrates, such as condoms even when no ejaculation has taken place. Dandruff, a clinical alteration of skin with “orthokeratotic clumps with minute parakeratotic foci” found in dermatological pathologies,\textsuperscript{20} is also a suitable substrate for DNA extraction if detected at a scene of crime.

Body fluids of forensic interest (other than blood, saliva, or sperm) which contain scarce amounts of DNA usually include urine and plasma. When the material is dry or semidry in the form of a stain or smear on fabric, it can be treated as blood stains or collected by swabbing if on a body. Though less frequent, it does happen that urine or plasma/serum (without the cellular components of blood) must be tested to verify whether the sample has been attributed to the correct person. An example may be urine testing for steroids in the sports industry, where positive results usually provoke contestation of whether the sample actually belongs to that person. Protocols for DNA extraction from liquids such as urine\textsuperscript{21} and plasma\textsuperscript{22} have been published.

Hair and body hair are other sources of DNA, although these substrates are controversial as most literature sources suggest that extraction of DNA is only possible from the bulb. However, there is at least one reference to extraction of DNA from hair shafts, but this refers to mitochondrial DNA.\textsuperscript{18} Recent studies have shown that appropriately examining the microscopic structure of hair, as well as diagnosing its growth phase, is crucial. Telogen hairs are most commonly found at the scene of crime, as the average human will shed 50–100 hairs during daily activities. Anagen/catagen hair bulbs and translucent sheath tissue are excellent candidates for nuclear DNA examination, whereas telogen hair clubs should not be submitted initially for such analysis, but should be saved for other tests (for example morphological comparative studies), before being subjected to grinding to a powder for DNA analysis.\textsuperscript{23}

Scalp hair is usually found on-site, on clothes and on bodies, and is easily collected using sterile forceps.

Pubic hair from the perpetrator of rape is usually found in the genital areas and on underwear of the victim and is collected and tested in the same manner. Pubic combing of suspected rape victims should always be performed in order to isolate suspicious hair that does not belong to the victim.

In murder cases, evidence such as hairs and fibers can be obtained from the body with strips of adhesive tape. Such tape fragments must then be carefully scanned for possible sources of the perpetrator’s DNA.

### 2.4 Dirty Material with Scarce DNA

These substrates include sperm, saliva and blood stains, nails and feces. With these substrates, not only are there small amounts of DNA, but there are also large quantities of organic and inorganic contamination from endogenous and exogenous sources, and from other substances. For example, nail scrapings, blood stains or swabs may contain soil, snot or other inorganic contaminants which can easily be present at a forensic scene. The method for extracting DNA must therefore prioritize on recovering small quantities of material, as well as on eliminating the inorganic components that may inhibit PCR.

Feces are peculiar in that they comprise a complex mixture of diverse microorganisms, digested food residues, mucus, and enzymes. All these must therefore be removed prior to PCR, especially bilirubin and bile salts which are strong PCR inhibitors.\textsuperscript{24}

### 2.5 Formalin-fixed and Paraffin-embedded Tissues, and Stained Smears on Slides

Tissues in formalin and paraffin also constitute a problem. Paraffin must be removed prior to DNA testing and formalin has deleterious effects on the DNA while fixation is taking place, as it alters its chemical structure.

Formaldehyde oxidizes to formic acid which acts as a reducing agent. At a concentration of 4% (usually the minimum at which it is used) formaldehyde breaks the purine–pyrimidine hydrogen bonds resulting in rapid and irreversible denaturation of DNA by hydrolysis of the N-glycosidic bonds which release the purine residue, followed by gradual hydrolysis of the phosphodiester bonds between nucleotides; cross-links between protein and DNA also occur.\textsuperscript{25} Paraffin seems to do less damage chemically, but tissue sections must be deparaffinized by dissolving, usually in octane, and then the DNA extracted with standard techniques, or the tissue simply digested.\textsuperscript{26} Specific methods involving phenol/chloroform also exist for dealing with formalin-fixed tissues. Extraction from these kinds of tissues is more frequent in scenarios pertaining to natural history and archaeology, although its applications are becoming increasingly frequent in paternity cases and malpractice suits, where a fixed piece of tissue may be the only reasonably well-preserved substrate left of a putative father. Similarly, histopathology sections and fixed tissue samples may be crucial in verifying whether there has been a specimen mix-up and therefore a wrong diagnosis.

At times, and for similar reasons, it may be necessary to extract DNA from stained cytological smears. Studies
have shown, at least with Papanicolau, May Grunwald Giemsa, hematoxylin and eosin and Baecchi stains,\(^{(27)}\) that this can be successful.

### 2.6 Calcified Tissues (Bone and Teeth)

The presence of a mineral matrix on to which DNA adsorbs requires the extraction process to overcome the bonds between minerals and DNA. These materials currently present one of the greatest challenges in forensic (and archaeological) DNA analysis.

Once remains have reached the skeletal stage, it is obvious that considerable degradation and usually soil contamination have occurred. Dry bone (and to a lesser extent tooth) exhibit large amounts of high-molecular-weight microbial DNA due to bone-dwelling organisms. There are also contaminants of humic acid and tannins derived from the soil. All these factors inhibit PCR and must be eliminated.\(^{(28)}\) For skeletal material, various groups in the field of microbial ecology and paleogenetic biology have implicated a plethora of inhibitors, namely Maillard reaction products or chemically altered carbohydrates, residues of porphyrins, damaged DNA, bacterial (nontarget) DNA, and soil components such as fulvic and humic acid, tannins, or complexing ions like iron (Fe\(^{++}\)). Although the common trend is to think of inhibitors as being “outside the substrate”, it is now being realized that they may be endogenous to the sample. Collagen, particularly human collagen type I, has been proved to be a potent PCR inhibitor.\(^{(29)}\)

However, the real challenge with calcified tissues (dry bone and teeth) lies in the binding interactions of the hydroxyapatite matrix that chemically stabilize DNA, thereby aiding its survival, but making it difficult to extract. The mechanisms of such interaction must be known in order to devise proper extraction methods for DNA from calcified tissues.

Bones and teeth are usually crushed and powdered by using liquid nitrogen in specific mills, though one could envisage that violent crushing may actually damage DNA. Decalcifying the bone or tooth does not seem to increase the yield of DNA; in fact, some studies have shown that it actually reduces the yield.\(^{(30)}\)

In the case of dry bone, it is still not known whether cortical or trabecular bone is the better substrate for extracting DNA. Cortical bone contains only bone cells (osteocytes, osteoblasts, and osteoclasts) and cells from vessels and nerves running through the Haversian canals. Trabecular bone additionally contains possible bone marrow residues in between the trabeculae, which may actually increase the amount of extractable cellular material, although it may also bring along the problem of greater quantities of cell debris that need to be purified.

Whichever type of bone is preferred, pulverisation seems to be the chosen form for extraction, as it maximizes exposure of the bone to extracting agents, a very important step considering the strong bond between DNA and mineral.

For teeth, the pulp should be the main source of DNA. If one considers the morphology of a tooth, the pulp chamber is the only dental tissue with nucleated cells. Neurovascular tissue here should be the best source of DNA and some authors therefore recommend extracting the pulp. However pulp morphology goes through a series of postmortem alterations which may make it impossible to distinguish the pulp from the pulp chamber walls and neatly pull it off (it usually has a film-like appearance and elastic or spongy consistency that, in fresh samples, makes it easy to tease out with clean forceps). In cases when it has disappeared or turned into a crystalline or sandy substance adhering to the walls of the pulp chamber, it is best to crush the entire tooth. It is possible in theory that DNA may still be present in old cementoblasts around the root or in extensions of odontoblasts in dentine, but the quantities are minimal. Teeth with endodontic treatment are particularly difficult, and it has been shown that the quantity of DNA recovered is 100-fold less than in a normal tooth.\(^{(31)}\) Therefore treated teeth, as well as immature permanent teeth with open roots and deciduous teeth with open or reabsorbing roots, should not be used.

### 3 DNA EXTRACTION

In order to clarify the various stages and methods of DNA extraction, this section comprises two basic parts, one dealing mainly with nonaffinity extraction methods and the other with affinity-based procedures. It must be kept in mind that the protocols given are mainly designed for PCR analysis although, depending on the substrate, some may also be used for the extraction of abundant, high-molecular-weight DNA useful for RFLP.

In general, extraction methods come under headings that bear the name of the type of chemical element involved, for example organic or inorganic. However, for this article, the simplest and most appropriate way of classifying DNA extraction techniques is by their essential mode of action. Methods directed towards all material but DNA (e.g. protein precipitation or the chelation of inorganic substances) are placed in the nonaffinity category, whereas those that specifically react with DNA and selectively extract it discarding everything else are considered in the affinity category. In the chemical sense, the term affinity relates to the property or attraction by which differing chemical elements or groups of
elements unite to form a new compound. In the case of affinity DNA extraction methods, the bonds that form between the DNA and the extracting reagent are reversible, and therefore allow subsequent release of the DNA.

Nonaffinity methods include:

- the well-known phenol/chloroform technique, frequently referred to as the main organic method;
- inorganic methods, based on the use of saturated salts;
- chelating agents, such as Chelex or ethylenediaminetetraacetic acid (EDTA);
- miscellaneous methods that include the use of other substances such as NaOH (alkaline extraction) and detergents.

All have in common the fact that they are designed for "extracting" non-DNA substances from the solution, leaving DNA behind to be concentrated and tested.

The affinity methods include techniques using silica particles, monoclonal antibodies and several commercial kits. All allow the user to work with material on to which DNA has been selectively bound.

Before specific extraction procedures are presented (meaning the purification and isolation of DNA), some important preliminary steps are considered. These are mainly the stages involving lysis of any surviving whole cells or other organic material and solubilization of DNA. In practice, this stage is already part of the DNA extraction procedure, and is included in a preliminary section because the rationale behind such a step is similar (as are the reagents) for most protocols. Differential lysis will also be dealt with.

Finally, this section describes the main nonaffinity and affinity methods of extracting DNA, based on the different principles by which they function. After a brief general consideration of the rationale, advantages, and disadvantages, two protocols for each method will be given: one for an easy substrate (e.g. fresh blood) and one for a difficult substrate (e.g. dry bone), when there is a distinction in the application of the method. Many combinations of extraction procedures exist. The protocols given in detail are those considered either to be the most widely tested for that particular category, or those which personal experience has suggested as being the optimal method at the present time. Tables of references are given for variations in protocols and other specific substrates. The previous comments regarding rapid advances in this field should be constantly borne in mind and the literature should be searched continually for more recent work on particular problems/substrates.

### 3.1 Cell Lysis, Protein Digestion and Solubilization of DNA

Although the main extraction step consists of the isolation of DNA prior to PCR, the preliminary phases, particularly that of lysis, are important.

These consist of dissociating the nucleic acids from their surrounding proteins and/or tissues, and the digestion of most material present in order to solubilize as much DNA as possible. Most techniques are based on incubation of the substrate in an extraction buffer (most commonly containing tris(hydroxymethyl)aminomethane (Tris)–HCl and EDTA). PK and a detergent (usually SDS) followed by what is usually considered the actual extraction phase or DNA isolation phase (e.g. phenol/chloroform extraction).

The role of the PK is to digest the protein, whereas the SDS is added to lyse cell membranes thus releasing the DNA. Other detergents that can be used include Nonidet and Triton X 100. Basically, many protocols in this sense are similar as they employ similar reagents and temperatures with varying incubation times (ranging from 30 min to 48 h), according to substrate and protocol.

Some protocols divide the lysis phase into two steps when fresh blood is the substrate: leukocyte separation by centrifuging the sample and/or by using chemical methods, including a red cell lysis buffer containing dextrose and a lysis agent; and pelleting the leukocytes. RNases have also been used in the past to eliminate any RNA present. The pH of these solutions and buffers is also important: at a pH of 5–6, the extraction of RNA is favored; at a pH of 8–9 both RNA and DNA are liberated. Sodium perchlorate has also been used in these preliminary steps – it is another reagent useful both for lysing and denaturing cellular proteins and, according to some authors, can replace the organic extraction phase. This is not a method of choice, but it has been successfully used on fresh and ancient material.

Finally, guanidine–HCl is sometimes used for cell lysis as it is highly denaturing. It has also been employed in conjunction with glass beads and sodium perchlorate.

Protocols for the lysis and digestion steps are given within the detailed extraction procedures identified in sections 3.2 and 3.3.

#### 3.1.1 Differential Lysis in Cases of Sperm-stained Material

In the special case of vaginal swabs and sperm stains where an abundant quantity of both sperm and female epithelial cells may be present, a differential lysis procedure (section 2) is necessary, prior to extraction. A suitable protocol is now briefly given.

When a vaginal swab from a rape case, for example, or a piece of fabric containing mixed male and
female secretions are the substrate, these are soaked in phosphate-buffered saline (PBS) in an appropriate tube according to the size, and incubated overnight at 4°C. The following steps should be followed:

1. Vortex briefly and remove the swab or fabric; spin down the cells at 2500g for 10 min at 4°C; save supernatant in a separate tube.

2. Wash the swab or fabric in 1.5 mL PBS/S (phosphate-buffered saline + 2% sarcosyl) in a microcentrifuge tube. Punch a small hole through the bottom of the closed tube, insert the tube into a second open tube and punch a hole in the lid of the tube containing the sample. Spin both tubes for 10 min at 1500g; the upper tube should contain the swab or fabric and the lower tube the buffer and cell pellet. Combine the cell pellet with the pellet from Step 1, saving the supernatant.

3. Wash the pellet twice in 1.5 mL PBS/S in a microfuge tube and spin it down for 10 min at 1500g. Resuspend the pellet in 50 µL PBS and remove 3–5 µL for microscopic analysis.

4. Add 500 µL PBS/PKS (proteinase K + sodium dodecyl sulfate) and incubate for 2 h at 50°C with mild agitation for lysis of vaginal epithelial cells. Recover sperm heads by centrifugation at 1500 g for 10 min at 4°C.

5. Save the supernatant (i.e. the female fraction) for further analysis of female DNA. Resuspend the pellet containing the sperm heads in 30 µL PBS and remove 2–3 µL for microscopic analysis.

6. Lyse the sperm heads (i.e. the male fraction) by adding 500 µL PBS/Lys and incubate for 3 h at 50°C with mild agitation.

7. Separately purify DNA from female and male fractions by the phenol/chloroform method described in section 3.2.1.

8. Transfer both supernatants to two separate Centri-con-30 microconcentrator tubes and purify DNA from salt, SDS, and contaminants with three washes with 2 mL distilled water each. Concentrate samples to a final volume of 100 µL.

### 3.2 Nonaffinity Extraction Methods

Nonaffinity methods are based on the indirect extraction of DNA by the selective precipitation of protein and other contaminants, or by chelation of inorganic substances (Figure 1). The main methods belonging to this category, which have excellent credentials for dealing with forensic material, are the phenol/chloroform method, Chelex resin and saturated salt procedures.

#### 3.2.1 Phenol/Chloroform

Since the beginnings of DNA analysis, the organic method of extraction par excellence has been phenol/chloroform; it is still the most popular method among the forensic community.

#### 3.2.1.1 Method Rationale, Advantages and Disadvantages

**Rationale.** The main mode of functioning is to remove the protein component thus purifying the nucleic acids; this is usually carried out by simply extracting aqueous solutions of the nucleic acids with phenol and/or phenol/chloroform. When dealing with complex mixtures of cell lysates and debris – and this is usually the case with forensic substrates – it is sometimes necessary to employ additional measures. In these cases, more protein can be eliminated by digestion with proteolytic enzymes (such as PK) which are active against a broad spectrum of native proteins (section 3.1), before the extraction with organic solvents. The standard way to remove proteins is to extract once with phenol, once with a 1:1 mixture of phenol–chloroform, and once with

---

**Figure 1** Mechanisms of nonaffinity methods where (a) the extracting agent (phenol/chloroform, salt or Chelex resin) pull away protein, metal ions, and components of cell walls, leaving (b) DNA in solution.
chloroform. Deproteinization is more efficient when two different organic solvents are used instead of one.\(^{(37)}\)

**Advantages.** This is the most tested method in forensics with protocols (including alternatives) for myriad substrates.

**Disadvantages.** The method does not eliminate other nonprotein contaminants as efficiently and may lower DNA yield because of the number of steps involved; when organic material is separated from the double-layer solution, some of the aqueous DNA-containing layer is lost with it, although this loss may be diminished by piercing a hole through the tube and allowing the phenol to drip out or by using a pipet where the narrow tip has been cut off.\(^{(16)}\) Phenol and chloroform can be harmful both for the substrate and for the operator.\(^{(32)}\) It is possible that DNA may be damaged as a result of steric shearing during the multiple tube transfers necessary in this method.\(^{(38)}\) Furthermore, phenol is a well-known carcinogen and chloroform can cause liver damage.

### 3.2.1.2 Selected Protocol for Easy Substrate: Fresh Blood\(^{(16)}\)

**Materials.**

1. 50 mM KCl (for hypotonic lysis of erythrocytes).
2. Lysis buffer: 25 mM EDTA, 75 mM NaCl, 10 mM Tris–HCl pH 7.5. Add 200 mg per milliliter of PK immediately before use.
3. 10% (w/v) SDS.
4. Sodium acetate, sodium chloride, ethylenediaminetetraacetic acid (ANE) buffer: 10 mM sodium acetate, 100 mM NaCl, 1 mM EDTA.
5. Buffered phenol: use only crystallized phenol, dissolve in a water bath at 65 °C and add approximately 0.1–0.2 volume of ANE buffer until an aqueous phase forms above the phenol; add 0.01% 8-hydroxyquinoline (w/v solid crystals).
6. Chloroform/isoamyl alcohol: to 24 parts of chloroform, add one part of isoamyl alcohol.
7. 6 M NaCl.
8. 3 M sodium acetate, pH 5.2: dissolve 40.8 g sodium acetate in 80 mL distilled water, bring to pH 5.2 with concentrated acetic acid, and adjust final volume with water to 100 mL.
9. TE (tris(hydroxymethyl)aminomethane–ethylenediaminetetraacetic acid) buffer: 10 mM Tris–HCl, 1 mM EDTA, pH 7.5.
10. Twentyfold sodium citrate (SSC): 175.3 g NaCl, 88.2 g sodium citrate per liter, adjust to pH 7.0 with NaOH.
11. 0.2 M sodium acetate, pH 7.0.
12. 10 mg per milliliter PK stock solution: dissolve 10 mg PK in 1 mL of 10 mM Tris–HCl, pH 8.0 and store frozen in small aliquots.
13. PBS: 50 mM phosphate buffer, pH 7.4, 0.9% NaCl.
14. PBS/S: PBS + 2% sarcosyl.
15. PBS/PKS: PBS + 100 μg per milliliter PK + 1% SDS (=10 μL PK stock solution + 100 μL 10% SDS per milliliter PBS).
16. PBS/Lys: PBS + 100 μg per milliliter PK + 2% sarcosyl + 10 mM dithiotreitol (DTT) + 25 mM EDTA (=10 μL PK stock + 10 μL 1 M DTT stock 50 μL + 0.5 M EDTA stock per milliliter PBS/S).

**Method.**

(a) Purification of white blood cells

1. Place 10–15 mL EDTA blood into a 50-mL polypropylene tube. In addition, transfer two 0.5-mL aliquots of blood into 1.5-mL microfuge tubes as reference samples and then store them frozen at -20°C.
2. Add 50 mM KCl up to 50 mL, mix well, and incubate in water bath at 37°C for 10 min.
3. Spin for 10 min at 500 g in a clinical centrifuge at room temperature.
4. Remove the supernatant with a Pasteur pipet connected to a water jet or vacuum pump; leave the pellet intact.
5. Repeat Steps 2–4 once or twice until the pellet is free from red cells.
6. Add 15 mL lysis buffer and shake vigorously to resuspend the cell pellet.
7. Add 1.5 mL 10% SDS and mix carefully. The sample should now become very viscous because of cell lysis.
8. Incubate overnight at 37°C or at 55°C for 4–5 h.

(b) Organic phase of DNA extraction

1. Add 1 volume buffered phenol to the PK-digested cell extract and mix the aqueous and organic phases carefully to achieve a homogeneous suspension; avoid vigorous shaking.
2. Spin for 10 min at 1500 g in a clinical centrifuge at room temperature.
3. The aqueous phase containing the DNA is on top and the phenolic phase is below. Transfer the aqueous phase to a fresh 50-mL polypropylene tube using a widebore glass pipet. The interphase containing proteins and protein DNA complexes may also be transferred at this step.
4. Add 1 volume of a 1:1 mixture of phenol and chloroform–isoamyl alcohol (24:1) and extract as described in Steps 1–3.
5. Add 1 volume of chloroform/isoamyl alcohol and repeat the extraction as described in Steps 1–3. At this step, avoid transferring any residual protein debris from the interphase.

(c) DNA precipitation
1. After organic extraction add 0.1 volume of 3 M sodium acetate and 2 volumes of ice-cold absolute ethanol.
2. Mix carefully without vigorous shaking. The DNA should precipitate by forming viscous strings and finally a compact pellet which may float on top of the solution.
3. Use a glass hook to recover the floating DNA (authors’ variation).
4. Rinse the DNA pellet attached to the glass hook twice in 70% ethanol to remove excess salt.
5. Dry the pellet briefly in the air and resuspend the DNA in an appropriate volume (300–500 µL depending on the size) of TE (1 in 10 in distilled water).
6. Incubate the sample for 1 h at 65°C or overnight at 37°C in a water bath to dissolve the DNA. If the sample is still very viscous, add more TE (1 in 10 in distilled water) and incubate again at 65°C until a homogeneous solution is obtained.

3.2.1.3 Selected Protocol for a Difficult Substrate: Dry Bone This protocol is modified from Cattaneo et al.\(^{39,40}\)

**Materials.**
1. Extraction buffer: 10 mM Tris–HCl pH 8.
2. 0.1 M EDTA pH 8.0.
3. 20 µg mL\(^{-1}\) RNase.
4. PK 20 µg mL\(^{-1}\).
5. 0.5% SDS.
6. 10 M ammonium acetate.
7. Phenol.
8. Chloroform.
9. Isoamyl alcohol.

**Method.**
1. Add powdered bone tissue slowly to approximately 10 volumes of extraction buffer in a 50-mL centrifuge tube. Add RNase to a final concentration of 20 µg mL\(^{-1}\).
2. Incubate at 37°C for 1 h.
3. Add PK to a final concentration of 100 µg mL\(^{-1}\); incubate at 50°C in a water bath for 3 h. Swirl the viscous solution periodically.
4. Cool the solution to room temperature. Add an equal volume of phenol equilibrated with Tris–HCl (pH 8) and gently mix the two phases by slowly swirling the tube end over end for 10 min. Separate the two phases by centrifugation at 2500 rpm for 15 min at room temperature.
5. With a widebore pipet (0.3 cm) slowly draw the DNA into the pipet to avoid disturbing the interface and transfer the viscous aqueous phase to a clean centrifuge tube and repeat the extraction with phenol/chloroform and then with chloroform/isoamyl alcohol.
6. After the third extraction transfer the aqueous phase to a fresh tube and add 0.2 volumes of 10 M ammonium acetate and two volumes of ethanol at room temperature and swirl the tube until the solution is thoroughly mixed.
7. Centrifuge the DNA down to a pellet.
8. Allow the pellet to air dry, then dissolve in sterile filtered distilled water.

3.2.1.4 Variations in the Protocol and References for Other Substrates Although the phenol/chloroform method has disadvantages, it has been reported as giving useful DNA for PCR from most substrates. Few studies have been performed comparing phenol/chloroform with other extraction methods. However, one study by the present authors showed that, as far as DNA yield and PCR success were concerned, inorganic methods (section 3.2.2) were equal if not better than organic methods with difficult substrates such as dry bone.\(^{39}\)

One other point that should be mentioned is that some authors have added extra postextraction concentration or purification steps. After extraction of DNA, various methods can be used to concentrate the end solution. Some workers prefer to use miniconcentrators, others to pellet the DNA down by centrifugation and resuspend it in the desired quantity of sterile filtered distilled water or deionized distilled water. Other purification steps mainly involve isolation of the molecular weight region of interest by electrophoresis of the PCR product, for example on agarose gel, cutting it out, and re-extracting it by boiling.\(^{39}\) These extra steps may be included at the end of most types of DNA extractions.

Table 1 lists, in chronological order, some major references in the forensic and archaeological fields, where phenol/chloroform has been used successfully to extract

DNA from various substrates; protocols may vary from the ones mentioned above. Points of interest, when present, are listed on the right.

3.2.2 Precipitation with Salts

Methods involving the use of salts are widely employed in blood transfusion and clinical scenarios where abundant clean samples are available. Although rarely used in forensic laboratories, recent literature has shown them to be as valuable with some forensic substrates as phenol/chloroform and give DNA yields that could be adequate for PCR and RFLP.

3.2.2.1 Method Rationale, Advantages and Disadvantages

Rationale. The rationale is that certain inorganic reagents, mainly salts, will precipitate proteins, and therefore act very similarly to phenol/chloroform. The cellular proteins are salted-out by dehydration and precipitation with a saturated salt solution.
Advantages. Compared to organic methods, the techniques are quicker and cheaper and much less toxic.

Disadvantages. They still do not eliminate all PCR inhibitors and considerable amounts of protein may be retained.

3.2.2.2 Selected Protocol using Saturated NaCl for Easy Substrate: Fresh Blood

Materials.
1. Lysis buffer: (10 mM Tris–HCl, pH 7.6; 2 mM Na$_2$EDTA, 400 mM NaCl).
2. SDS at 10%.
3. PK at 20 mg mL$^{-1}$.
4. Saturated NaCl 6 M.
5. Absolute ethanol.
6. TE buffer (10 mM Tris–HCl, 0.2 mM Na$_2$EDTA, pH 7.5).

Method.
1. Buffy coats of nucleated cells obtained from anticoagulated blood are resuspended in 15 mL polypropylene centrifugation tubes with 3 mL nucleic lysis buffer.
2. Cell lysates are digested overnight at 37°C with 0.2 mL SDS and 50 µL PK.
3. After digestion is complete, 1 mL of saturated NaCl is added to each tube and shaken vigorously for 15 s, followed by centrifugation at 2500 rpm for 15 min.
4. The precipitated protein pellet is left at the bottom of the tube and the supernatant containing DNA transferred to another 15-mL polypropylene tube.
5. Two volumes of absolute ethanol at room temperature are added and the tubes rotated until DNA is precipitated (forming a medusa).
6. The precipitated DNA strands are removed with a plastic spatula or pipet and transferred to a 1.5-mL microcentrifuge tube containing 100–200 µL TE buffer.
7. The DNA is then allowed to dissolve for 2 h at 37°C before being stored at −20°C.

3.2.2.3 Selected Protocol using Saturated Sodium Acetate for Difficult Substrate: Dry Bone

Materials.
1. Buffer (10 mM Tris–HCl pH 7, 10 mM Na$_2$EDTA, 50 mM NaCl).
2. PK (20 µg mL$^{-1}$).
3. SDS at 10%.
4. 100% isopropanol.
5. 70% ethanol.

Method.
1. 1.5 g pulverized bone are incubated in a polypropylene tube containing 3 mL white cell lysis buffer with the addition of 25 µL PK and 50 µL SDS in a water bath overnight at 42°C.
2. 1 mL saturated sodium acetate is then added and the tube shaken manually for 30 s and then centrifuged at 4000 g for 10 min.
3. The supernatant containing the DNA is then transferred to a new polypropylene tube; 4 mL 100% isopropanol are added and mixed for at least 10 min to precipitate the DNA before centrifugation at 4000 g for 10 min.
4. The supernatant is discarded; the remaining whitish-yellow pellet of DNA suspended in 250 µL 70% ethanol, is transferred to a 1.5-mL microcentrifuge tube and centrifuged at 13000 g for 10 min.
5. The pellet is dried in an incubator at 37°C, reconstituted in 250 µL sterile filtered distilled water and the resulting DNA solution divided into 20-µL aliquots which can be stored at −20°C until required for testing.

3.2.2.4 Variations in Protocol and References for Other Substrates

The literature does not provide as wide a variety of protocols for salt extraction in forensic scenarios as for the other methods. However, a previously mentioned comparative study between phenol/chloroform and saturated salt precipitation was performed for the extraction of DNA from putrefied cadavers. The latter seemed the better extraction method, although a post-PCR purification step still had to be added in order to get typable DNA.

3.2.3 Chelating Methods

3.2.3.1 Method Rationale, Advantages and Disadvantages

Rationale. The rationale is that the active reagent will bind to inorganic substances and clear the extract of PCR inhibitors in this category. Although simple chelating methods exist which employ the properties of substances such as EDTA to neutralize certain ions, one of the main chelating methods involves the use of Chelex. Chelex is a resin composed of styrene–divinylbenzene copolymers containing paired iminodiacetate ions that act as chelating groups in binding polyvalent metal ions. It has a high selectivity for divalent ions and...
differs from ordinary ion exchangers because of higher bond strength.\textsuperscript{61} It has been postulated that boiling a sample in the presence of Chelex prevents the degradation of DNA.\textsuperscript{62} Metal ions which act as catalysts in DNA breakdown at high temperatures and at low ionic strength are chelated and inhibited from this action.

Advantages and Disadvantages. The technique is simple and rapid and does not involve multiple transfer tubes. The Chelex resin removes impurities and the alkaline pH disrupts the cell membranes resulting in the release of DNA. It does not have a particularly selective activity on protein and can be unreliable unless relatively large amounts of DNA are present.

3.2.3.2 Selected Single Protocol Using Chelex for an Easy Substrate: Fresh Blood\textsuperscript{61}

Materials.
1. Chelex 100.
2. Sterile deionized water.

Methods on Whole Blood and Blood Stains.
1. Pipette 1 mL sterilized deionized water into a 1.7-mL microcentrifuge tube.
2. Add 3 µL whole blood or a piece of blood-stained material (3 mm square) and incubate at room temperature for 15–30 min.
3. Prepare a 5% Chelex solution in sterile deionized water.
4. Centrifuge samples for 3 min at 10 000 g in a microcentrifuge to pellet the red blood cells.
5. Carefully remove all but 20–30 µL of the supernatant and discard. Leave the substrate and pelleted material in the tube.
6. Resuspend the pellet in 5% Chelex 100 to a final volume of 200 µL.
7. Incubate at 56 °C for 30 min.
8. Vortex at high speed for 5 s.
9. Incubate in a boiling water bath for 8 min.
10. Vortex at high speed for 5 s.
11. Centrifuge samples for 3 min at 10 000 g to pellet the Chelex 100 resin, substrate, and remaining tissue.
12. The extracts are now ready. For short-term usage, store at 2–8 °C on the Chelex 100 resin. For long-term storage (over 1 month), the extracts should be centrifuged and the supernatant removed from the Chelex 100 resin and stored in a new tube at −20 °C.

3.2.3.3 Selected Protocol using Chelex for a Difficult Substrate: Bone\textsuperscript{61}

Materials. As described above.

Method.
1. Prepare a 5% Chelex 100 suspension in sterile deionized water.
2. Add 200 µL of 5% Chelex 100 suspension to a 1.7-mL microcentrifuge tube.
3. Place 0.5 g crushed bone tissue directly into the Chelex 100 suspension.
4. Incubate at 56 °C for 30 min.
5. Continue with the protocol for whole blood (Steps 8–12).

3.2.3.4 Variations in Protocol and References for Other Substrates It has been reported that Chelex can also be used to extract DNA from hair, seminal stains, saliva, and postcoital samples.\textsuperscript{63} Its advantage with saliva stains, as compared to phenol/chloroform, has been verified,\textsuperscript{64} although in this case a modified version of the Chelex method was adopted, which involved pre-extraction with PK and incubation at 56 °C and 100 °C plus microconcentration of the solution.

References to other chelation protocols on different substrates are given in Table 2.

3.2.4 Miscellaneous Methods

Other less popular nonaffinity methods exist, some of which rely on the use of detergents. The CTAB (cetyltrimethylammonium bromide) and DTAB (dodecyltrimethylammonium bromide) method can be considered a valuable, relatively recent technique for DNA extraction. After incubation in DTAB, a cationic detergent which lyses the cell membrane and denatures protein, chloroform is added to further denature and deproteinize the extract, which is then centrifuged; the DNA-containing aqueous layer is kept and CTAB is added to it. The purpose of CTAB, another detergent, is to precipitate DNA. These reagents are highly toxic and have featured in few reports in the field of forensics.

Alkali extraction is another alternative and is among one of the simplest strategies – whereas the primary structure of DNA is relatively stable in alkaline solution, other proteins are efficiently solubilized due to the ionization of aspartic, glutamic, cysteic, and tyrosine residues. Proponents of the method state that efficient extraction of DNA from whole blood can be performed with alkaline treatment at room temperature in a time frame as short as 1 min. Alkaline extraction of buccal epithelial cells, blood and semen stains can be accomplished in 5–6 min at 75°C whereas liquid semen requires 30 min at 75°C. The technique involves incubating aliquots of whole blood (5 µL) with 20 µL of NaOH at temperatures ranging from ambient to 90°C for 60 min. The reaction is stopped by adding Tris–HCl, pH 7.5. Potassium hydroxide can be used as a substitute for sodium hydroxide.

Some authors have even suggested the use of anhydrous hydrogen fluoride to extract DNA from yeast and fungi, whereas others have reported extracting DNA from archaeological material by simply incubating bone powder in water or by incubating it in an extraction buffer.

3.3 Affinity Methods

The novelty of affinity methods is that they rely on the process of actively selecting, to varying degrees, the DNA by either a nonspecific or specific reaction, thus allowing the examiner to wash out all other substances.

3.3.1 Nonspecific Affinity Methods

The main nonspecific affinity methods employ (a) glass (silica) beads in combination with isothiocyanate bound to guanidium or (b) magnetic beads from Dynal coated with a substance(s) specific for DNA but which is not revealed in the manufacturer’s data sheets (dealt with briefly in section 3.3.3).

3.3.1.1 Method Rationale, Advantages and Disadvantages of the Silica Beads Procedure

Rationale. The silica glass particle method (sometimes called the glass milk or silica gel method) is based on glass particles actively attaching to isothiocyanate which is itself bound to guanidium. It has been hypothesized that the positively charged amine groups on the guanidium act as the link to the negatively charged phosphate groups on DNA. Once DNA is bound to the glass particles, it can be repeatedly washed and spun, as the glass particles will retain the attached DNA and allow elimination of other material and inhibitors (Figure 2). However other mechanisms of DNA binding to silica have been suggested. These may involve chaotic salt disruption of the water structure around negatively charged silica, allowing a cation bridge to form between it and the negatively charged phosphate backbone of DNA; this reaction is reversible in low salt concentrations.

Advantages and Disadvantages. The main advantage is that, contrary to nonaffinity methods, DNA is selectively bound (even if only temporarily) to a substrate (glass) that can be repeatedly washed. Once it has been satisfactorily cleansed, the DNA can be eluted. This offers a much better chance of purifying DNA from PCR inhibitors.

The disadvantages lie in the fact that when a great deal of contaminant is present, it may sterically hinder the adsorption process of DNA on to the glass substrate. In addition, the silica method preferentially recovers high-molecular-weight DNA and so may fail to recover any DNA from samples in which molecules are present but in a highly fragmented form (less than 100 bp).

3.3.1.2 Selected Protocol Using Silica Particles for any Substrate

This protocol is modified from Höss and Pääbo.

Materials.

1. Extraction buffer (4 M guanidine thiocyanate, 0.05 M Tris–HCl pH 7.6, 0.01 M EDTA, 1% Triton X-100).
2. The silica suspension: 12 g Sigma S-5631 is mixed with 100 mL sterile filtered distilled water and left to sediment for 24 h; the top 86 mL of liquid (water) are removed and discarded. The volume is made up with distilled water to 100 mL and the silica resuspended and left to sediment for 5 h. Finally, the top 88 mL are removed and discarded. 120 µL of 10 M HCl are added to the sediment, resuspended and aliquoted in sterile eppendorf tubes and kept at 4 °C.
3. Wash buffer (extraction buffer with 150 µL sterile filtered distilled water added).

Methods for any Substrate.

1. The pulverised bone (1 g) or shredded blood stain or 1 mL whole blood is incubated in 1 mL extraction buffer at 60 °C for 1 h.
2. Centrifuge at 4000 g for 5 min.
3. 500 µL of supernatant are added to 500 µL extraction buffer and 40 µL silica suspension.
4. Rotate the mixture for 10 min at room temperature.
5. Centrifuge at 4000 g for 15 min.
6. Wash twice with wash buffer.
7. Wash twice with 70% ethanol.
8. Centrifuge at 4000 g for 5 min.
9. Dry the resulting silica pellet for 10 min at 56 °C, then resuspend in 65 µL sterile filtered distilled water and leave at 56 °C with occasional mixing.
10. Centrifuge the suspension at 4000 g for 3 min and transfer the supernatant to a clean tube.
11. The remaining silica pellet is resuspended, centrifuged for a second time and the supernatant removed and pooled with the previous one.
12. The DNA solution (pooled supernatants) is finally centrifuged at 6000 g for 5 min and the supernatant removed and stored at −20 °C.

3.3.1.3 Variations in Protocol and References for Other Substrates Glass milk has been used in clinical settings for the recovery of DNA from minute amounts of serum and plasma (50 µL) and also after PCR in order to further purify DNA. The silica glass milk method is currently the optimal one for archaeological material and is very likely to be useful in the forensic field when dry bone is being extracted.

In a comparative study between Dynal DNA-direct™, sodium acetate precipitation and glass milk extraction methods, on dry bone and blood stains over 40 years old, the present authors found that amplifiable DNA was obtained more often with the glass milk technique, although the quantity of DNA was less.

Table 3 presents a series of references from authors who have used different silica affinity protocols on various substrates.

3.3.2 Specific Affinity Methods: Monoclonal Antibodies

This method employs anti-dsDNA IgG-coated beads.

3.3.2.1 Method Rationale, Advantages and Disadvantages

Rationale. Immunoaffinity methods are those based on the use of antibodies devised specifically for detecting and attaching to DNA. They are scarce and, up to the time of writing, only one protocol has been published, although a full description of the development of the method is available.

Briefly, the technique consists of the production of a monoclonal antibody to double-stranded DNA; it then uses magnetic beads coated with the antibody to specifically select DNA from a solution (Figure 3). Although contamination of the monoclonal anti-DNA with murine and bovine DNA might occur during preparation, neither reduced sensitivity due to blocked antibody sites nor false positive PCR reactions from species cross-reactivity have been observed. Contamination with human DNA, always a potential problem with such a sensitive method, can be avoided by meticulous technique and by including antibody-coated
beads on their own in every experiment as a negative control.

Advantages and Disadvantages. The great advantage of this method is that the DNA is selectively bound by a monoclonal antibody. This represents the maximum specificity one can achieve for selecting DNA from a solution and positive results can be obtained with as little as 0.005 ng per microliter of DNA. Another advantage is that the beads–anti-DNA–DNA complex can be put directly into the PCR solution.\(^\text{84}\)

The disadvantage lies in the fact that the method has not yet been tested sufficiently on forensic material, and, at the moment, is quite expensive. Also, although the method is very specific, it does not yield large volumes of DNA.

3.3.2.2 Protocol Using Anti-DNA Antibody-coated Magnetic Beads on a Single Substrate\(^\text{84}\)

Materials.

1. Murine monoclonal antibody (IgG2A class) to dsDNA are bound on to paramagnetic beads coated with anti-mouse IgG by incubating at 20°C for 2 h. The beads are then washed and resuspended to a concentration of 4 \times 10^8 per milliliter.
2. Digestion buffer (0.5% Na\(_2\)EDTA, 0.1 M Tris base, pH 7.8, 0.1 M NaCl, 1% Nonidet P-40).
3. PK (20 mg per milliliter).
4. Fetal calf serum.
5. Isotonic saline.
6. Distilled water.

Methods.

1. Test samples (e.g. 0.05 mL fresh blood, 1 cm\(^2\) blood-stained gauze, 0.5 g powdered bone) are incubated at 56°C in 3 mL digestion buffer and 100 μL PK for up to 36 h for bone (30 min for fresh blood).
2. Supernatants are collected and approximately 20 \times 10^5 antibody-coated beads are added and incubated at 20°C with constant mixing for varying periods (2 h for blood, 24 h for bone).
3. The beads are recovered magnetically and washed three times in 3% fetal calf serum in
isotonic saline and once in sterile filtered distilled water.

4. The beads are then suspended in either sterile filtered distilled water or with the reaction mixture and immediately subjected to PCR (approximately $16 \times 10^3$ beads per reaction).

To our knowledge no other protocol has been devised based on immunoaffinity. Preliminary studies of this method on dry bone and blood stains over 40 years old have given positive results for HLA DR loci, suggesting that it has a promising future in forensic DNA analysis.

3.4 Commercial Methods

Commercial kits are being increasingly used and several provide protocols for forensic substrates. They are usually based on an affinity mechanism. Although one cannot comment on their specific mode of action, they seem reliable on scarce forensic substrates in some cases. Detailed protocols for their use are supplied with the kits. The ones usually referenced in the forensic literature are DNA direct (Dynal, QIAamp® (QIAGEN), Prep-A-Gene® and GeneClean® DNA extraction kits.

Dynabeads DNA Direct™ are uniform superparamagnetic polystyrene beads designed for the simple and rapid isolation of DNA from crude materials. The process relies upon the rapid adsorption of the released DNA on to the surface of the Dynabeads. The DNA–bead complex is then separated magnetically and washed. One study compared the DNA yield from feces between phenol/chloroform and Chelex methods in the extraction of DNA from blood stains and mixed sperm/epithelial substrates. If the substrate is not extremely scarce, mixed DNA, seem to be the techniques of choice for difficult cases, recent work has suggested that the future is taking place with difficult substrates, where DNA is scarce and contamination abundant. In these cases, recent work has suggested that the future lies in affinity methods – this would seem a more logical approach and is supported from a physical and chemical point of view. The extracted DNA is purer and present in relatively greater amounts (with respect to non-DNA contaminants).

Affinity methods, such as the use of glass particles or (even better) monoclonal antibodies, which select out DNA, seem to be the techniques of choice for difficult substrates. If the substrate is not extremely scarce, mixed procedures could be used (e.g. phenol/chloroform and glass beads). The only drawback of affinity methods is that they have not yet been routinely tested on most forensic substrates and so do not have a proven record. It is for forensic research to remedy this and, together with data from other disciplines concerning the physical and chemical interaction of DNA with various reagents, to produce tailor-made extraction methods for the plethora of scenarios encountered daily in forensic practice. Only with proper extraction procedures will subsequent DNA analysis be successful.

4 CONCLUSIONS

The aim of this article is two-fold. First, it evaluates the difficulties in DNA extraction for PCR technology in forensic scenarios, considers the versatility of DNA survival, and stresses the need for the extraction method to relate to the substrate. Second, it provides at least two protocols (one for easy substrates and one for difficult ones) selected from the existing forensic literature for each basic extraction method. It is difficult to provide a method of choice for some situations, and techniques are evolving and improving all the time. Nevertheless some general conclusions can be drawn from our own experience and from examining the existing literature.

Methods involving phenol/chloroform have been used since the beginning of RFLP and PCR technology, and therefore have a better tested record with the widest variety of substrates. Although they have been very successful, they are dangerous, toxic, time-consuming and involve many steps. Furthermore, they are not directly selective for DNA. At present, DNA extraction methods in forensic analysis seem to be going two ways:

- For clinical material, with fresh, abundant sources of DNA, extraction presents no problems – salting out methods are just as successful as methods using organic solvents and are far less toxic. Commercial extraction kits provide a suitable alternative.

- The most interesting evolution in extraction methods is taking place with difficult substrates, where DNA is scarce and contamination abundant. In these cases, recent work has suggested that the future lies in affinity methods – this would seem a more logical approach and is supported from a physical and chemical point of view. The extracted DNA is purer and present in relatively greater amounts (with respect to non-DNA contaminants).

Emission spectroscopy, which in the forensic science context historically has meant (carbon) arc spectroscopy, is occasionally still employed in paint examination and some other trace evidence areas, but has largely been replaced by atomic absorption (AA), Fourier transform infrared (FTIR), gas chromatography/mass spectrometry (GC/MS) and other analytical techniques. Notwithstanding its intrinsically very high sensitivity, molecular fluorescence spectroscopy is not utilized as a general technique of forensic analysis either, because spectra tend to be broad and featureless. Fluorescence spectral examination may occasionally be used in areas such as document examination, specifically for ink differentiation in instances of document alteration, but fluorescence spectra as such tend to pertain primarily to the arena of research. This is not to say, however, that the photoluminescence phenomenon is not exploited in criminalistics, the examination of articles of physical evidence recovered from the crime scene. Indeed, it is widely and effectively employed in tagging or labeling modalities and via the inherent fluorescence itself of trace evidence. Fluorescence-based approaches to authentication of currency and passports, identification of valuables, origin specification of gun powders and explosives, surveillance, and so on, are less directly pertinent to forensic science. These areas of fluorescence tagging will thus not be dealt with in detail. In criminalistics, photoluminescence is today the mode par excellence for ultrasensitive latent fingerprint detection. It is also employed in detection of body fluids, visualization of fibers, ink discrimination, and so on. Thus, the focus in this article will be on visualization and imaging. We begin, however, with discussion of the basic molecular photoluminescence phenomenon and description of some useful spectroscopic measurements, namely luminescence and excitation spectra, and luminescence lifetime determination by time-gated and phase-resolved techniques. These set the stage for the latest advances in photoluminescence visualization in physical evidence processing, with emphasis on fingerprints, the most prominent photoluminescence application in forensic science.

1 INTRODUCTION

The emission of light by substances can have various causes, among them heat (thermoluminescence or incandescence), electrical charge (electroluminescence, cathodoluminescence) and chemical reaction (chemiluminescence), as in the reaction of luminol with blood. However, for our purposes the most important origin of the luminescence is the prior absorption of light, giving rise to photoluminescence. The phenomenon was studied long before its quantum mechanical underpinnings were understood. Early on, two categories of photoluminescence were distinguished on the basis of lifetime, namely fluorescence, associated with short lifetime, and phosphorescence, with long lifetime. The slowness concept of distinction between the two light emissions evolved
over time, with a trend toward shorter decay times. At first, phosphorescence involved emission with a lifetime longer than roughly a few seconds. Today, emissions called phosphorescence may involve lifetimes shorter than microseconds. The distinction between fluorescence and phosphorescence is placed on a less arbitrary footing as follows. The photoluminescent (typically organic) molecules of interest to good approximation can be thought of as being two-electron systems. When the molecule is in its ground state, the spectroscopically active electrons fill the highest occupied molecular orbital (HOMO). Their spins must be antiparallel to satisfy the exclusion principle and the corresponding state is thus a singlet state. When one of the two electrons resides in the lowest unoccupied molecular orbital (LUMO), the molecule is in the excited state that gives rise to photoluminescence. If no spin flip has taken place in the process of electron promotion to LUMO, the excited state is a singlet state, and the decay to the (singlet) ground state, accompanied by the emission of a photon, is termed fluorescence. If a spin flip has taken place (which is quantum mechanically legal because the two electrons no longer occupy the same spatial orbital), the excited state is a triplet state and the decay back to the ground state via emission of a photon is termed phosphorescence. We generalize the distinction between fluorescence and phosphorescence on the basis of the spins of the two states between which the light-emitting transition takes place. The electric dipole operator which describes the photon emission does not operate on spin. When states of the same spin multiplicity are involved, we thus have fluorescence. Otherwise, we have phosphorescence, with violation of the basic \( \Delta S = 0 \) spin selection rule, hence the longer lifetime. This definition is not universally followed. For instance, one often hears of fluorescence of lanthanides, even though the involved states differ in spin multiplicities \( (2S + 1) \), often even by spin quantum number change greater than 1. Recombination and trap luminescences in semiconductors are a different matter still. Thus, the term photoluminescence will be utilized in general, with the term fluorescence reserved for the transition between molecular singlet states.

In photoluminescence visualizations associated with examination of articles of evidence, one is concerned with the optimization of the wavelength of the incident light to maximize the intensity of the photoluminescence of interest, and with the wavelength of the photoluminescence itself, for optimization of contrast with background fluorescences that almost invariably are present. Excitation spectral measurement aids the first of the above two optimizations and emission spectra pertain to the second one. In some instances, background fluorescence is extremely intense and of the same color as the photoluminescence of interest. In such instances, time-resolved visualization may be employed for the suppression of the background. Photoluminescence lifetime measurements define the optimization of this background removal.

2 SPECTRA\(^{(1,2)}\)

The optimization of the excitation that produces a photoluminescence typically involves absorption spectroscopy in solution. If the sample of interest does not scatter light appreciably and is reasonably transparent, absorption spectroscopy of solid samples may be performed also. However, in the forensic science context one often has to contend with opaque samples and samples that contain a number of absorbing species. Thus, excitation spectroscopy is often performed to obtain the same spectral information one would ordinarily obtain from an absorption measurement.

2.1 Excitation Spectrum

Figure 1 shows the block diagram of a generic set-up for excitation spectroscopy. The light source depends on the spectral range to be covered, but might typically be a xenon arc lamp. Monochromator 1, the excitation monochromator, is wavelength-scanned while monochromator 2, the emission monochromator, is set at a fixed wavelength, at or near the photoluminescence maximum of the sample. The photoluminescence intensity variation versus excitation wavelength provides the same spectral information as absorption spectroscopy, excepting absolute optical density. This does not matter since the excitation optimization only calls for relative absorbance monitoring. The light source/excitation monochromator combination is on occasion replaced by a tunable laser.

![Figure 1](image-url)
The emission monochromator is sometimes replaced by a band-pass filter.

### 2.2 Emission Spectrum

The set-up shown in Figure 1 is also applicable to measurement of emission spectra. In this case, however, monochromator 1 is set at a fixed wavelength (at which the photoluminescent material absorbs well) while monochromator 2 is scanned. The photomultiplier tube (PMT) shown in the figure and associated signal processing electronics, such as a photon counter perhaps, may be replaced by an optical multichannel analyzer, which basically is a charge-coupled device (CCD), in the form of a linear array of the photosensitive elements. With this replacement, scanning of the emission monochromator is no longer required because the array covers the spectral range of interest. Again, the light source/monochromator combination may be replaced by a laser. The emission monochromator may be replaced by a wedge filter, namely a variable band-pass filter.

### 3 LIFETIMES

Photoluminescence lifetimes of interest to us are typically measured either by time-gated or phase-resolved techniques. We are not here concerned with picosecond or femtosecond techniques. For our purposes, time-gated techniques are best suited to lifetimes longer than microseconds and phase-resolved techniques are used for shorter lifetimes, down to the subnanosecond regime.

#### 3.1 Time-gated Measurement

Figure 2 depicts the general approach to time-gated photoluminescence lifetime measurement and Figure 3 shows a representative experimental arrangement. The gate, of adjustable width, is scanned through the dark period of the chopped excitation, shown in Figure 3 as employing a laser. The output of the boxcar averager or similar signal processing instrument is then an exponentially decaying signal.

#### 3.2 Phase-resolved Measurement

The essence of the phase-resolved technique for photoluminescence lifetime measurement is shown in Figure 4. $\phi$ is the phase shift between excitation and emission, $w$ is the modulation angular frequency, $2\pi f$, where $f$ is the modulation frequency, $\tau$ is the luminescence lifetime, $B/A$ is the modulation depth of the excitation light and $b/A$ that of the luminescence (with average intensities normalized to be equal as drawn in the figure), and $m$ is the demodulation factor. The experimental set-up is similar to that of Figure 3. However, the excitation light is now not chopped on-off, but is modulated sinusoidally in intensity. When the sample of interest displays multiple lifetimes, the phase-resolved measurement is made over a range of modulation frequencies. Lifetimes are extracted by computer analysis of the phase shifts or demodulation factors. The boxcar averager shown in Figure 3 is replaced with a phase and frequency sensitive instrument, essentially a lock-in amplifier in function.

### 4 PHOTOLUMINESCEENCE IN FINGERPRINT DETECTION

When a finger is pressed against an article, about a tenth of a milligram of material is typically deposited, forming a latent fingerprint. About 99% of this is water, which soon evaporates to leave behind about a
illuminating the article under scrutiny with the light from imaging approaches. Current routine detection involves blue-green range. Lasers are mandatory in time-resolved detection in these spectral ranges but ordinarily operate in the UV, are useful in special instances. Ar-lasers can operate in the blue-green, a convenient range because powerful and user-friendly light sources for the deep UV, lasers in particular. Fortunately, however, there are fluorescent components (riboflavin being one of them) in the residue that absorb in the blue-green, a convenient range because powerful and user-friendly lasers operating in this range were already in existence when photoluminescence detection of fingerprints as a general technique began to be explored in 1976. Inherent fingerprint fluorescence detection is a useful procedure, more so because it is nondestructive, such that all other fingerprint processing approaches can subsequently still be employed. Inherent fingerprint fluorescence detection has been used successfully in numerous cases, but is applicable only when background fluorescence is weak even under excitation with powerful Ar-lasers. The detection applies to old as well as fresh prints. In casework, the oldest print was developed 41 years after the fact. In the author’s laboratory, a print dating to the early 1860s was detected. When there is prohibitive background luminescence, procedures such as dusting with luminescent powder, staining with luminescent dye and chemical treatments that lead to photoluminescent products are employed. Truly difficult situations call for time-resolved techniques.

4.1 Light Sources

Not only the presence but also the spatial distribution of minute quantities of material is probed in fingerprint detection. Given that photoluminescence intensity is proportional to excitation intensity (barring complications that are not operative in fingerprint work), photoluminescence detection is thus often performed using high power lasers, such as argon-ion lasers that deliver 5–20 W in the blue-green region and CW (continuous wave) frequency-doubled Nd : YAG (yttrium aluminum garnet) lasers with output powers of several watts at 532 nm. Albeit at the sacrifice of sensitivity, band-pass-filtered arc lamps are often utilized as well. Their virtues are price and portability (although portable lasers of comparable power, several hundred milliwatts, are available also). For evidence examinations not concerned with fingerprints, lamp systems offer much flexibility in terms of light color tuning. For fingerprint work, the blue-green region is mostly of interest. Near ultraviolet (UV), and at times even deep UV, are useful in special instances. Ar-lasers can operate in these spectral ranges but ordinarily operate in the blue-green range. Lasers are mandatory in time-resolved imaging approaches. Current routine detection involves illuminating the article under scrutiny with the light from the laser, dispersed with a lens or a fiber-optic cable to form an illumination spot a few centimeters in diameter, or with the filtered lamp. The article is visually examined (in a darkened room) through goggles that block the scattered or reflected illumination light but transmit the fingerprint luminescence (long-wavelength pass filter). Once a fingerprint is observed, it is photographed through the same type of filter as in the observation goggles. Band-pass filters are additionally employed occasionally for background fluorescence suppression.

4.2 Inherent Fingerprint Fluorescence

Fingerprint residue absorbs primarily in the deep UV (wavelengths shorter than 300 nm), not surprisingly given the abundance of small organic molecules in the residue. This is not a generally useful wavelength domain because the resulting photoluminescence would be expected mostly to occur in the near-UV, not visible to the eye. Moreover, there is a dearth of intense and user-friendly light sources for the deep UV, lasers in particular. Fortunately, however, there are fluorescent components (riboflavin being one of them) in the residue that absorb in the blue-green, a convenient range because powerful and user-friendly lasers operating in this range were already in existence when photoluminescence detection of fingerprints as a general technique began to be explored in 1976. Inherent fingerprint fluorescence detection is a useful procedure, more so because it is nondestructive, such that all other fingerprint processing approaches can subsequently still be employed. Inherent fingerprint fluorescence detection has been used successfully in numerous cases, but is applicable only when background fluorescence is weak even under excitation with powerful Ar-lasers. The detection applies to old as well as fresh prints. In casework, the oldest print was developed 41 years after the fact. In the author’s laboratory, a print dating to the early 1860s was detected. When there is prohibitive background luminescence, procedures such as dusting with luminescent powder, staining with luminescent dye and chemical treatments that lead to photoluminescent products are employed. Truly difficult situations call for time-resolved techniques.

5 PHYSICAL FINGERPRINT TREATMENTS

A number of fingerprint treatments for photoluminescence have been developed since the advent of inherent fingerprint fluorescence detection. They have mostly been designed to respond to the blue-green excitation suitable for inherent fingerprint fluorescence excitation, such that one light source suffices for most purposes.
5.1 Dusting with Fluorescent Powder

Numerous fluorescent powders are available commercially. They can also be made at home rather easily by blending fluorescent dye with iron filings, for example, to produce fluorescent magnetic powder. Successful casework involving dusting for fluorescence detection of fingerprints includes the famous Polly Klaas (abduction/murder, 1993) case. As with dusting generally, the approach is applicable only to relatively fresh fingerprints because the powder adherence to fingerprint residue suffers when fingerprints dry.

5.2 Staining with Fluorescent Dye

In much the same way in which dye staining can improve visualization in the cell studies of biology, fluorescent dyes can attach preferentially to fingerprint residue. This mode of fingerprint detection was recognized early on but suffered from the problem of fingerprints being washed away when the article was sprayed with the dye solution or when it was immersed in the solution. With the advent of (methyl or ethyl) cyanoacrylate ester fuming in the early 1980s, however, staining with fluorescent dye, notably rhodamine 6G, became the most successful bread-and-butter fingerprint detection methodology. The cyanoacrylate fuming process was first explored in Japan and was brought to the USA by personnel of the US Army Criminal Investigation Laboratory. The volatilization of the cyanoacrylate ester, the active ingredient in Superglue® and similar adhesives, is achieved by heating or placement of drops of the glue onto cotton pads that are soaked with NaOH and left to dry prior to the glue application. Commercial pouches (Hard Evidence, Loctite Corp., Newington, CT) that deliver the fumes on opening are especially useful for field work. The fuming is done in a humid atmosphere. A white polymer then forms on fingerprints and stabilizes them such that the subsequent dye staining does not wash them away. In the absence of humidity, the polymer formed is clear, as it is when the fuming utilizes a vacuum chamber, an approach that is gaining use. In the latter two situations, staining, preferential to the polymer, and fluorescence visualization are mandatory for fingerprint detection. In the former approach, visibly developed white prints may develop. From the perspective of the dye staining, however, it is not necessary that the Superglue® polymerization be that extensive. The dye staining, by dipping or spraying, typically utilizes a methanol solution. If the staining of the article is excessive, a neat methanol rinse can be applied to wash off excess dye. However, this potentially risky procedure is not usually necessary if the dye concentration is kept low, about 10⁻⁵ M. Coumarin dyes are sometimes employed, as are analogs of crystal violet for fingerprints on the sticky side of adhesive tapes.

Lanthanide-based formulations are explicitly taken up below. A number of commercial dye formulations are in use. Rhodamine 6G, however, remains an unsurpassed option because it is a laser dye (thus endowed with very high fluorescence quantum yield) that is superbly matched to Ar-laser excitation and that is very good in its fingerprint selectivity. Old as well as fresh fingerprints are amenable to the dye staining approach. The Nightstalker case is an example of successful fingerprint detection by rhodamine 6G staining/laser examination. Vapor dye staining procedures are reported in the literature for processing difficult surfaces (such as cloth and skin) but are not currently employed routinely.

6 CHEMICAL FINGERPRINT TREATMENTS

Dusting and staining approaches are applicable only to reasonably smooth surfaces since the processing of porous items, such as paper for instance, will not be fingerprint selective but will cover the whole article. Examination of articles of this kind calls for chemical procedures that involve reaction with a fingerprint constituent leading to a photoluminescent product.

6.1 Ninhydrin and Ninhydrin Analogs

Ninhydrin (1) was introduced to the fingerprint field in 1954. The compound was first prepared by Ruhemann in 1910 and was recognized by him to be an amino acid assay reagent, a use it has been put to widely since then in biochemistry. Since the early 1960s, ninhydrin has become the workhorse of chemical fingerprint processing. The reagent usually is first dissolved in methanol or ethanol and the solution is then diluted with a volatile carrier solvent in order to minimize bleeding of fingerprint detail. A few grams of ninhydrin per liter of solvent system (about 90% volatile carrier) is a typical concentration. For many years, 1,1,2-trichlorotrifluoroethane...
(also known as fluorisol, freon TF, freon 113, CFC 113) was the preferred volatile carrier. However, since it is ozone depleting, it is now replaced by solvents such as petroleum ether, heptane, HFE 7100\(^\text{\textregistered}\) (the hydrofluoroether 1-methoxy-nonafluorobutane, 3M product), and so on. Acetic acid (a few milliliters) is sometimes added to counteract the alkalinity of some papers. Ethyl acetate may be added as well to counteract the esterification reaction between the alcohol and acetic acid that is accompanied by the formation of water as an undesirable by-product. The reagent concentrations are not at all critical. The reaction requires ambient humidity and is slow at room temperature, taking several hours. It can be expedited in an incubator. The ninhydrin–amino acid product (2), referred to as Ruhemann’s Purple, is unfortunately not fluorescent, even under optimized orange dye laser excitation. This can be remedied by a subsequent treatment with zinc chloride.\(^{15}\) This salt is dissolved to saturation in methanol and diluted with a volatile carrier, much like the ninhydrin. The reaction with Ruhemann’s Purple requires ambient humidity and is nearly instantaneous. The product formed (3) is orange in color, and thus from the absorption perspective well suited to blue-green excitation. The product displays an intense, broad fluorescence peaked in the yellow. The fluorescence increases substantially at low (near 77 K) temperature. The low-temperature fingerprint development (including photography) is relatively straightforward.\(^{15}\) An example of the sensitivity gain of the (room temperature) fluorescence detection with ninhydrin/zinc chloride as compared to the corresponding traditional ninhydrin development of the same sample is shown in Figure 5. The sensitivity gain shown translates to the casework scenario.\(^{16}\) Ninhydrin/zinc chloride has become routine in casework since the mid-1980s. It is applicable to old as well as fresh prints.

Benzo(\(f\))ninhydrin (4) functions much like ninhydrin but yields a green product instead of a purple one when reacting with amino acid. When this is followed by zinc chloride and fluorescence examination, the excitation maximum shifts to about 530 nm, well matched with the frequency-doubled Nd : YAG laser.\(^{17}\) Moreover, the (orange) fluorescence intensity is substantially higher at room temperature than that obtained (under comparably intense 490-nm excitation) with ninhydrin/zinc chloride. It is of high quantum yield such that little is gained by the additional complication of liquid nitrogen work. In terms of excitation and fluorescence color, 5-methoxyninhydrin (5) resembles ninhydrin, but in its fluorescence quantum efficiency in concert with zinc chloride it has the superior characteristics of benzo(\(f\))ninhydrin.\(^{18}\) The benzo and methoxy analogs of ninhydrin are commercially available (Aldrich) but are comparatively expensive. In the author’s laboratory, they have nonetheless supplanted ninhydrin in casework because of sensitivity. Other ninhydrin analogs of excellent characteristics and 1,2 indanedione analogs of ninhydrin have been reported, but are not available commercially.

![Figure 5](image)

**Figure 5** Fingerprint on paper developed by ninhydrin only (a) and by subsequent application of zinc chloride followed by laser examination (b).

in casework because of sensitivity. Other ninhydrin analogs of excellent characteristics and 1,2 indanedione analogs of ninhydrin have been reported, but are not available commercially.

6.2 1,8-Diazafluoren-9-one

The compound 1,8-diazafluoren-9-one (6), referred to as DFO,\(^{19}\) is employed much like ninhydrin. However,
its reaction with fingerprint amino acid requires elevated temperature (100°C). The product responds to green excitation and yields an orange fluorescence. In the author’s experience, it is (at room temperature) intermediate in sensitivity between ninhydrin/zinc chloride and the two ninhydrin analogs/zinc chloride mentioned above. DFO has been in routine use as a fluorogenic reagent since the early 1990s in a number of law enforcement agencies.

6.3 Miscellaneous Treatments

Dimethylaminocinnamaldehyde or para-dimethylaminocinnamaldehyde (DMAC) or (PDMAC) was investigated in the late 1970s for fluorescence detection of fingerprints because it was thought to react with urea, a major component of eccrine secretions. The reagent is well known to forensic biologists for use in urine stain detection. While its fluorescence use for fingerprint work was successful, it was supplanted by ninhydrin/zinc chloride and later DFO. However, it may be making a comeback because it offers the prospect of dry fingerprint development by vapor or contact procedures, and thus has prospects for processing fingerprints on items, such as cloth for instance, that do not lend themselves to the application of solutions. Several heme-catalyzed procedures, such as merbromin plus hydrogen peroxide, exist for fluorescence detection of blood prints. Fluorescein, and even ninhydrin/zinc chloride and DFO can be effective in blood print detection as well. No truly effective procedures for fingerprint detection on skin exist at present.

7 FINGERPRINT TREATMENTS OF FUTURE POTENTIAL

We concern ourselves here with approaches to latent fingerprint detection that have the potential of becoming universal strategies, that is applicable to fingerprints on all kinds of evidence, rather than with incremental modifications of fingerprint procedures such as those discussed above.

7.1 Lanthanide-based Fingerprint Detection

A number of the lanthanide ions (which typically exist in the +3 valence state in compounds), notoriously europium and terbium, emit with high quantum yields and also with long lifetimes, in the millisecond domain. Unfortunately, these ions absorb poorly, such that emission intensities tend to be rather low. In the biochemical arena and also in the fingerprint field, the remedy for this problem has been to chelate the lanthanide ion with a ligand that absorbs well and that transfers its excitation energy to the lanthanide ion, basically by the Forster energy transfer process. The basic scheme is depicted in Figure 6 for the case of europium.

The sensitizing ligand may result from a reaction with fingerprint residue, in which case for example, the counterpart to ninhydrin/zinc chloride has been obtained. The complex may be prepared in solution to lend itself to application in the dye staining mode, akin to rhodamine 6G. The complex may be blended with dusting powder. All three modes have been demonstrated in fingerprint work, with a variety of sensitizing ligands, and with amino acid and lipid sensitive chemistries. However, pervasive problems persist in connection with fingerprints that are not fresh. The most salient virtue of the lanthanide strategy is its utility in concert with time-resolved imaging to suppress the obnoxious background fluorescences which all too often hamper fingerprint detection. Europium complexes, where the emission is...
in the red and typically is excited by UV light absorbed by the sensitizing ligand, often lend themselves nicely to background suppression by simple optical filtering because of the large absorption–emission wavelength discrepancy. The current most effective application of lanthanides to fingerprint detection involves the staining approach using europium with thenoyltrifluoroacetone and/or ortho-phenanthroline as sensitizing ligands. Preparation of lanthanide complexes may be as simple as mixing a europium salt in solution, such as EuCl$_3$·6H$_2$O, with an excess of ligand, although a stoichiometric proportion of the bidentate ligands is often chosen, keeping in mind that the full coordination of the Eu$^{3+}$ ion is nine-fold.

7.2 Photoluminescent Semiconductor Nanoparticles

The application of photoluminescent semiconductor nanoparticles (also referred to as nanocrystals, quantum dots, or nanocomposites) to latent fingerprint detection is likely to be the next milestone in the evolution of the field, for a number of reasons:\(^2,23\)

1. Photoluminescent semiconductor nanocrystals, such as CdS and CdSe, emit with efficiencies comparable to those of laser dyes.

2. The luminescence lifetimes are on the order of $10^{-7}$ s. This is a range very well suited to phase-resolved imaging for background fluorescence suppression.

3. The excitation and emission wavelengths can be tailored by adjusting the size of the nanocrystal.

4. CdSe nanocrystals can be encapsulated with ZnS or silica,\(^24\) and can be made soluble in both polar and nonpolar media. The encapsulation may permit the attachment of ligands designed to bind to constituents of fingerprints.\(^25\)

5. The nanocrystal surfaces may be functionalized with ligands designed for selective binding to fingerprints. Nanocrystals may be prepared within voids of dendrimers, which, in turn, may be functionalized for selective attachment to fingerprints.\(^26\)

Indeed, recent preliminary work\(^27,28\) suggests that selective fingerprint tagging with photoluminescent semiconductor nanocrystals and dendrimers is feasible. Figure 7 shows the photoluminescence detection (under blue-green Ar-laser excitation) of a fingerprint fumed with cyanoacrylate ester and then stained (in heptane solvent) with CdS nanocrystal functionalized with dioctyl sulfosuccinate.

8 TIME-RESOLVED IMAGING\(^2\)

The suppression of the background fluorescence that often inhibits fingerprint detection typically uses a CCD camera equipped with a microchannel plate image intensifier which can be gated on-off or modulated sinusoidally. In the former instance, the luminescence excitation source is chopped on-off and the camera is synchronized to be on in the light-off portion of the chopping cycle, with a delay past laser cut-off such that the background has already decayed by the time the camera turns on. The camera turns off before the next laser-on cycle portion. This is the imaging counterpart to the lifetime measuring scheme of Figure 2, but with a gate that is not scanned and that has a width that spans most of the chopper dark period. When luminescence lifetimes shorter than about $10^{-8}$ s are involved, the light chopping becomes expensive and difficult because full extinction in the light off portion of the cycle becomes difficult at the requisite high chopping frequencies. For that domain, phase-resolved imaging becomes of interest because it is not necessary for the light modulation depth to be perfect when phase shifts are probed. Now the imaging involves a phase delay between the sinusoidal light modulation and the sinusoidal image intensifier gain modulation. This is the imaging counterpart to the scheme of Figure 4. There are variants in which the light modulation and camera gain modulation are at slightly different frequencies such that the image information is extracted at the low difference-frequency in a manner reminiscent of the frequency mixing used in radios, for instance.

**Figure 7** Fingerprint on soft drink can developed by cyanoacrylate fuming followed by staining with CdS nanocrystal solution.
9 FLUORESCENCE IN TRACE EVIDENCE ANALYSIS

Curiously, fluorescence spectroscopy as such is not widely exploited in criminalistics. However, fluorescence visualization is gaining frequent use in various areas, such as document examination, where infrared fluorescence has been utilized for some time already, fiber analysis, and trace evidence more generally. Typically, the article under scrutiny is simply illuminated and visually inspected for fluorescence. Photography and visual comparisons may be made. We do not consider here highly specialized areas such X-ray fluorescence or chemiluminescence.

9.1 Fiber Analysis

The scrutiny of fibers encountered at the crime scene proceeds primarily by comparison optical microscopy, to examine for color, shape and texture. Polarization microscopy may also be done to determine index of refraction and birefringence. Additional modes of examination include visible and infrared absorption microspectrometry and chromatography of fiber dye content.\(^{29-31}\) Currently, the utilization of photoluminescence is confined to finding of fibers at the scene via their fluorescence. Otherwise elusive fibers can be found in this way. In principle, excitation and emission spectroscopy can be done on single fibers without much difficulty. However, this is presently not a tool used routinely in fiber analysis. Because fibers come in a wide range of colors, a correspondingly wide range of excitation wavelengths is called for to produce fluorescence adequately. White light source/band-pass filter or monochromator combinations are thus more commonly employed than lasers which operate at a single wavelength or a set of discrete wavelengths. An Ar-laser/dye laser combination, with the Ar-laser operable in the near-UV and blue-green, is very effective, however. As a rough rule of thumb, yellow compounds call for blue excitation and display green to yellow fluorescence, red or orange materials call for green excitation and show yellow, orange or red fluorescence, and blue or green substances require orange to red excitation to display red or near-infrared emission. Colorless or white materials call for UV excitation and typically emit in the near-UV or blue.

9.2 Document Examination

In the area of document alteration, where the interest is to distinguish between writings made with different inks that are of the same color and thus difficult to distinguish by ordinary inspection, plugs of writing are sometimes removed from the document and subjected to thin-layer chromatography (TLC) or the writing is subjected to infrared luminescence examination under visible excitation, most often in the green, especially in examination of black inks. We inquire into the reason for this excitation/emission situation.\(^{2}\) Generally, absorption and emission do not occur at the same color, even though the same molecular electronic states (ground, first excited singlet) are involved in both phenomena. Instead, the emission occurs at a longer wavelength than the absorption. This is referred to as Stokes shift, and arises from a physical distortion of the molecule after absorption and is related also to vibrational relaxation/wave function overlap considerations. The general scheme is shown in Figure 8(a). Instead of emitting light, a (donor) molecule may transfer its excitation energy to a nearby (acceptor) molecule, as depicted in Figure 8(b). This process, referred to as Forster energy transfer, is not the same as emission of a photon by the donor molecule followed by subsequent absorption of that photon by the acceptor molecule, a process sometimes referred to as self-absorption. Both processes are active in particles of colloidal dimensions, comprised of many molecules in close vicinity to each other, such as ink particles. The energy transfer or self-absorption processes may involve identical molecules or different species. The latter is of most interest in inks made up of dyes of several colors.

The excitation may be most effective at a wavelength where a large number of the ink molecules absorb, i.e. in the green on average for black ink (ideally composed of yellow, magenta and cyan molecules). The emission, on the other hand, comes only from the molecules with the lowest energy gap between the ground and first excited singlet states. The emission is thus typically in the near-infrared. Because of self-absorption/energy transfer, most of the molecules in the ink particle do not emit. Since the emission process generally has quantum efficiency less than one, the net luminescence is also far weaker than it would be if the molecules in the ink particle were far apart from each other. The separation of molecules is in document examination achieved by TLC. Once the components of an ink are thus separated,
visibly fluorescent components that otherwise would lose their energy via self-absorption/energy transfer may be detected on the TLC plate. TLC sensitivity can be substantially enhanced in this way. If there is not enough altered writing to permit TLC, in situ fluorescence examination can be much improved by painting the writing with a clear and rapidly drying lacquer that serves to separate ink components slightly to suppress the quenching via self-absorption/energy transfer. This mode of ink examination is currently not routinely performed, however. In situ excitation and luminescence spectroscopies are not generally done either, even though they are not difficult to do in principle. Direct visual examination (with visible and infrared photography) is the most widely utilized fluorescence application in document work. It is often effective in recovering erased or obliterated writing. In the latter case, examination from the back side of the page may be effective.

9.3 Miscellaneous Trace Evidence Detection

Numerous cases of contamination of probative value on articles of evidence, detected by fluorescence, have been reported, including transferred printing, glass fragments, paint, and so on. Often, the detection is serendipitous, but fluorescence crime scene examination for general purposes is becoming more common. For example, deliberate fluorescence detection is at times attempted to find biological fluids, semen stains in particular. The visualization utilizes blue-green or UV excitation. Once such stains are found, they are processed by the customary biological techniques of forensic science. The application of fluorescence to DNA profiling is currently routine only in quality assurance of digestion and electrophoresis, by staining with fluorescent dye, most notably ethidium bromide. The profiling as such in the RFLP (restricted fragment length polymorphism) approach utilizes radioactive tagging, and colorimetric spot development is typical in PCR (polymerase chain reaction) processing. However, the fluorescence approaches common in (nonforensic) DNA sequencing are rapidly gaining use in criminalistics. Glass fragments and paint chips are sometimes examined by fluorescence comparisons but the fluorescence detection is usually followed by more standard techniques of analysis. Laser examination has been performed on cyanide-laced Tylenol capsules. PDMAC is occasionally applied to some drug examinations. However, the analysis of poisons or drugs does not usually employ photoluminescence techniques, generally relying instead on absorption spectroscopy, chromatography and mass spectrometry. For drugs, color and microcrystalline tests are also used, as preliminary examinations. In explosives and firearms examination, techniques such as electron microscopy (with X-ray elemental analysis) and color tests for metal or explosive residue on the skin of a suspect are typical, rather than fluorescence methodology.

# Immunoassays in Forensic Toxicology

David E. Moody  
*University of Utah, Salt Lake City, USA*

---

## 1 Introduction

### 1.1 Forensic Toxicology

Forensic toxicology encompasses the determination of the presence and concentration of drugs, other xenobiotics and their metabolites in physiological fluids and organs and the interpretation of these findings as they may impact on legal issues. These include medical examiner investigations, driving under the influence and other transportation accident investigations, workplace pre-employment, random and for-cause drug testing and judicial monitoring of arrestees and parolees. Similar techniques are employed in emergency room clinical toxicology and to monitor the efficacy of substance abuse treatment. The introduction of immunoassays into forensic toxicology in the early 1970s has had a major impact on the speed and efficiency that samples can be screened for the presence of certain drug classes. For the most part, forensic toxicologists use commercial immunoassays directed primarily towards abused drugs. Commercial immunoassays developed for therapeutic monitoring of other drugs, veterinary drugs and pesticides, as well as immunoassays developed in research laboratories for specialized studies, may find a role in the forensic toxicology laboratory for specialized cases.

Most immunoassays used for forensic toxicology are competitive. An antigen structurally similar to the target compound is conjugated to a signalling molecule and competes with target drug in a sample for antibody binding. Immunoassays are also classified as homogeneous and heterogeneous. Homogeneous assays do not separate the original sample from the final detection sample. They must use a signal that changes when antibody is bound. Homogeneous immunoassays include enzyme immunoassay (EIA) (enzyme activity decreases when bound), fluorescent polarization immunoassay (FPIA) (emission in a polar field increases when bound) and kinetic interaction of microparticles in solution (KIMS) immunoassay (lattice formation inhibited when bound). Heterogenous immunoassays include radioimmunoassay (RIA) and enzyme-linked immunosorbent assay (ELISA) where unbound radiolabeled antigen and enzyme conjugated antigen, respectively, are removed from the sample before measurement. In general, the homogeneous immunoassays are more amenable to full automation, and thereby quicker throughput. The heterogenous immunoassays are less susceptible to matrix interference, and thereby more versatile with nonurine matrices.

While most commercial immunoassays have been developed for a urine matrix, they have been applied by forensic toxicologists to other matrices, including blood, hair, saliva, sweat, tissue homogenates, blood stains and most other physiological samples that may be of value in the investigation. The use of nonurine matrices must contend with two factors. With the exception of parenchymal tissues, the concentration of the target compound is often lower and the sensitivity of the immunoassay may be limiting. In addition, the nonurine matrix usually is much more complex in its composition. Sample pretreatments that range from simple deproteinations to multistep extractions to remove matrix components and/or concentrate the sample are often required. The heterogenous RIAs and ELISAs usually require less rigorous, if any, pretreatments.

Interpretation of immunoassay results must take into consideration the limits of detection of the assay, the cross-reactivity of the antibody(ies) and the potential for interference. Appropriate controls should be included to demonstrate adequate signal separation from blanks (drug-free sample in the same matrix). The concentration of the low control is often determined by the sensitivity

of the assay, or in workplace testing programs by administratively determined cutoffs that draw the line between a negative and presumptive positive. The ability of the antibody to detect compounds other than the target compound (its cross-reactivity) can be a useful characteristic or, when the drugs that can be confirmed are limited, a nuisance. The amphetamines, barbiturates and benzodiazepines, in particular, all have a number of licit (and for amphetamines illicit) analogs that could be present in a sample. Cross-reactivities are antibody-source (i.e. manufacturer) dependent. Further testing to determine the immunoreactive compound often requires rigorous methodologies. In some instances, the potency of the drug and its poor cross-reactivity make detection by immunoassay difficult (e.g. nitrosobenzodiazepines). Interference in immunoassays may arise from compounds that appear in the matrix during disease states, or those that are intentionally added to a sample in the hope of negating a positive test. These act through many different mechanisms and may decrease or increase the immunoassay test result.

Immunooassays have added an extremely useful tool to the forensic toxicology investigation. They can be used to screen rapidly a large number of samples for the potential presence of a drug group. With rare exceptions (emergencies, limited sample volume), their use without a confirmation assay (e.g. gas or liquid chromatography/mass spectrometry (LC/MS)) is unwarranted, as it leads to a risk of improper test result interpretation.

1 INTRODUCTION

1.1 Forensic Toxicology

Forensic toxicology encompasses the determination of the presence and concentration of drugs, other xenobiotics and their metabolites in physiological fluids and organs and the interpretation of these findings as they may impact on legal issues. Forensic toxicology has grown in scope from investigations conducted by the medical examiner's office to include driving under the influence and other transportation accident investigations, workplace pre-employment, random and for-cause drug testing and judicial monitoring of arrestees and parolees. Similar techniques are employed in emergency room clinical toxicology and to monitor the efficacy of substance abuse treatment. The capabilities of the forensic toxicologist to detect and quantify drugs, other xenobiotics and their metabolites have grown along with the field of analytical chemistry. The introduction of the RIA by Yalow and Berson in 1959\(^1,2\) was followed in the early 1970s by the introduction of immunoassays into forensic toxicology. This form of analysis has had a major impact on the speed and efficiency that samples can be screened for the presence of certain drug classes.

For the most part, forensic toxicologists use commercial immunoassays directed primarily towards abused drugs (Table 1). These immunoassays will be the primary subject of this article. Commercial immunoassays have also been developed for therapeutic monitoring of other drugs. Some of these assays can also be of great use to the forensic toxicologist investigating causes of death or toxic injury (Table 2). The routine use of these will vary from laboratory to laboratory, as some laboratories will depend upon other screening methods such as thin-layer chromatography (TLC) or gas chromatography/mass spectrometry (GC/MS) screens to extend their qualitative detection. Some therapeutic drug assays may not be used routinely, but may be called upon if the medical history dictates (e.g. epileptic deaths and anticonvulsants). Other immunoassays have been developed for the detection of drugs specific to veterinary toxicology and the detection of pesticides for environmental monitoring. In addition, a number of immunoassays with limited distribution have been developed in research laboratories for specialized studies. All of these assays may find a role in the forensic toxicology laboratory for specialized cases, but they will not be discussed further in this article.

This article has been prepared so that a reader unfamiliar with immunoassays and/or their application to forensic toxicology can come away with a basic understanding

of how immunoassays work, their limitations and how they have been applied for studies in forensic toxicology. Much of the tabular material is, however, practically complete, with studies listed in chronological order. It is hoped that the inclusion of this material will make this article also of value to the experienced forensic toxicologist.

1.2 Principles of Immunoassay

Immunoassays require an antibody that is selective for the drug or drug group of interest (antigen), a label that will be part of the antibody antigen complex that emits a detectable signal and a means of detecting the signal. Immunoassays may be competitive (Figure 1), where the analyte competes with labeled analyte for the antibody, or noncompetitive, where the antibody, or a secondary antibody is labeled. The commercial immunoassays in use to detect drugs of interest to forensic toxicologists are competitive immunoassays.

Immunoassays can also be distinguished as heterogeneous versus homogeneous. Heterogeneous assays require the separation of bound from unbound antigen, while homogeneous assays do not require separation. In general, the separation step of a heterogeneous assay will remove the initial specimen matrix, and this in turn will reduce the number of potential interfering substances. Therefore, heterogeneous assays are considered more specific and sensitive. On the other hand, the additional steps required to perform a heterogeneous assay make total automation of the assay more difficult. Most homogeneous immunoassays are easily automated. The heterogeneous immunoassays in common use in the forensic toxicology laboratory are the RIA and the ELISA and the homogeneous immunoassays are the EIA, FPIA and KIMS immunoassay.

1.3 Introduction of Immunoassays into Forensic Toxicology

Urine drug testing had long been a tradition in the forensic toxicology laboratory for medical examiner studies and the extension of driving under the influence investigations since the increased drug use in the 1960s. Many techniques were employed. The introduction of TLC in the 1960s had a major impact. Two driving factors led to the introduction of immunoassays into the forensic (and clinical) laboratory. The first was the need for methadone treatment clinics to monitor drug use of the patients. The second, which was to have an overwhelming impact, was the use of drugs in the Vietnam war. Both dictated the need for rapid analysis of urine samples for morphine.

In 1970, Spector, at the Roche Institute of Molecular Biology, developed an RIA for morphine.\(^4\) A refinement of this RIA was then developed at Hoffman-La Roche that could be routinely used to measure morphine in urine and serum.\(^5\) The use of radioactive material in this assay, however, limited the sites where it could be performed. Leute et al. at Syva (formerly Synavac) developed an immunoassay that utilized antibodies directed towards morphine and electron spin resonance to detect morphine conjugated to a spin label, nitroxide radical.\(^6,7\) The spin of the unpaired electron in the nitroxide radical can be detected by electron spin resonance. The signal produced by a rapidly rotating (unbound) radical is sharp and distinct; it diminishes as the conjugated antigen is bound by antibody. This was named the free radical assay technique (FRAT).

Although initially developed for use by methadone clinics, this technique was seized upon by the US Army, and beginning in 1971 was used to screen military personnel in Vietnam. FRAT instrumentation was expensive. During the same time period, Adler et al. developed a hemagglutination-inhibition (HI) assay for morphine that was both rapid and simple.\(^8,9\) Syva then developed an EIA that had antigen conjugated to the enzyme lysozyme for detection of morphine in urine [enzyme-multiplied immunoassay technique (EMIT)].\(^10,11\) This assay could be performed on a number of commonly available laboratory instruments and thereby became readily usable by numerous forensic and clinical laboratories.

Although both the FRAT and HI methods were used and evaluated for a time,\(^12-14\) they did not gain sufficient favor to have a long-term impact. Both the RIA and EIA methods, however, became popular and were expanded to encompass the detection of a number of abused and therapeutic drugs.

2 IMMUNOASSAYS USED IN FORENSIC TOXICOLOGY

The commercial production of immunoassays that are used in forensic toxicology laboratories is a dynamic market, and some vendors advertise their products to a greater extent than others. The following sections are based on vendors that have come to the attention of the author (Table 3). The omission of any vendors does not imply any negative attributes towards their products, it simply demonstrates the author’s ignorance of their existence.

# 2.1 Homogeneous Immunoassays

## 2.1.1 Enzyme Immunoassay

EIAs are homogeneous immunoassays that utilize an antigen conjugated to an enzyme (Figure 2a) or enzyme fragment (Figure 2b). When the conjugated antigen is bound to antibody, the enzyme is less active or inactive. As the amount of target drug in a sample increases, it displaces the conjugated antigen, thereby activating the enzyme. The enzyme will then form product(s) from the substrate(s). Product formation is monitored with the detector at an absorbance selective for the product. The rate of product formation increases with the amount of target drug in the sample (Figure 2c).

Syva’s EMIT assays were the initial immunoassays available for EIA detection of drugs. The EMIT initially used lysozyme as the enzyme conjugate in urine assays. For serum therapeutic drug monitoring assays this was not practical because of endogenous lysozyme activity; glucose-6-phosphate dehydrogenase was used for these assays. Eventually, glucose-6-phosphate dehydrogenase was incorporated into the urine assays as lysozyme substrate was found to degrade with aging, some individuals (~2–4% of the population) were found to excrete endogenous lysozyme into their urine and a number of inhibitors of lysozyme were being encountered in tested urines. Malate dehydrogenase was also used for a time in the urine assays, but it also suffered from excretion of endogenous enzyme. The glucose-6-phosphate dehydrogenase reaction requires glucose-6-phosphate and nicotinamide adenine dinucleotide (NAD) as substrates. The formation of nicotinamide adenine dinucleotide (reduced form) (NADH) is monitored spectrophotometrically.

When the patent on EIA for drug detection lapsed, other companies entered this market. DRI, (a subsidiary of Sybron International Corp.) markets a number of EIAs that also use antigen conjugated to glucose-6-phosphate dehydrogenase. A different approach was taken by Microgenics (now also a subsidiary of Sybron International Corp.). They invented the CEDIA that uses recombinant DNA expressed fragments of β-galactosidase as the enzyme conjugate. Two enzyme fragments exist that are inactive by themselves; the smaller one is conjugated to the drug–antigen. In the unbound state, the fragments will freely associate and form active enzyme that forms product from the substrate, chlorophenol red β-D-galactopyranoside (Figure 2b). The rate of product formation increases with the amount of target drug in the sample.

The EIAs utilized in forensic toxicology laboratories are amenable to many different automated analyzers. The manufacturers should be consulted to see which
instruments have proven useful in their experiments. Use of other instruments, or modifications of the procedures are best accompanied by data that validate the modifications. A number of studies have been reported on the EMIT (Table 4), CEDIA and DRI assays (Table 5).

### 2.1.2 Fluorescent Polarization Immunoassay

The FPIAs for drug analysis are homogeneous immunoassays marketed by Abbott Diagnostics. The antigen is conjugated to fluorescein. The fluorescein is excited with light in a single plane (polarized light). When conjugated antigen is bound to the antibody, the rate of rotation of the complex is relatively slower, and more light is emitted. The unbound conjugated antigen rotates faster and emits less light (Figure 3a). As drug in the sample increases and more binds to the antibody, displacing the conjugated antigen, the amount of light emitted decreases (Figure 3b). Abbott’s FPIAs require dedicated instruments such as the TDx or ADx. These will be provided by Abbott as part of a reagent agreement. Representative studies of the TDx and ADx reagents for detection of abused drugs are shown in Table 6.

### 2.1.3 Kinetic Interaction of Microparticles in Solution

Roche Diagnostics markets a number of KIMS immunoassays for the detection of drugs. The antigen is...

conjugated to microparticles. When antibody binds the conjugated antigen, a lattice of microparticles will form. The lattice decreases as conjugated antigens are unbound owing to competition for antibody binding sites with target drug in the sample (Figure 4a). The greater the lattice formation, the higher is the absorbance, or the absorbance decreases as the target drug in the sample increases (Figure 4b). The KIMS immunoassays utilized in forensic toxicology laboratories are amenable to many different automated analyzers. The manufacturers should

A summary of the use of KIMS assays for detection of drugs of abuse in urine is presented in Table 7.

2.2 Heterogeneous Immunoassays

2.2.1 Radioimmunoassay

RIAs incorporate a radiolabeled antigen that competes for binding to the antibody with unlabeled drug in the sample. Most of the RIAs used in forensic laboratories use \(^{125}\)I-labeled antigens. \(^{125}\)I can be detected with gamma counters or liquid scintillation counters. Some specialty RIAs (e.g., fentanyl assays prepared by Janssen Laboratories) are available for drug analysis that use \(^{3}\)H-labeled antigens. These require a liquid scintillation counter. RIAs are heterogeneous assays and separation of the bound from unbound labeled antigen is required. For the common \(^{125}\)I-dependent assays, two separation methods have been used. The double antibody method is used for the RIAs that used to be marketed by Roche Diagnostics (Abuscreen), many of the RIAs marketed by DPC and all of the RIAs marketed by Immunalysis Corp. (the Immunanalysis drugs of abuse panel incorporates many of the reagents previously supplied by Roche Diagnostics as their Abscreen line of RIAs). Following the initial antigen–primary antibody complex formation, a second antibody specific for the primary antibody is added. This allows the formation of a precipitable lattice, that is pelleted by centrifugation (Figure 5a). DPC also markets RIAs for some drug groups with antibody attached to a plastic tube (Coat-A-Count RIAs). Here the antigen–antibody complex remains attached to the tube. Centrifugation is not required; the unbound material is simply decanted out of the tube (Figure 5b).

As the amount of drug in the sample increases, more of the radiolabeled antigen will remain in the unbound state; the amount of radioactivity in the pellet, or attached to the tube, decreases (Figure 5c). As the short half-life of the \(^{125}\)I-labeled antigens results in rapid loss of counts per minute (cpm) from one day to the next, comparison of RIA data usually depends upon use of the ratio of bound cpm to the cpm in a sample where the concentration of unknown drug is zero \((B/B_0)\) (Figure 5c).

Because they use radioactive materials, RIAs require special laboratory conditions for the safe storage, handling and disposal of the radioactive material. A related aspect of RIAs is the above-mentioned half-life of the radiolabel. \(^{125}\)I has a 60 day half-life that is essentially the shelf-life of the reagent. Although this limits the time over which the reagents can be used, it also makes storage of waste material simpler. After a number of half-lives the material can be more readily disposed of. \(^{3}\)H with a half-life of 12.4 years can be stored almost indefinitely, but will always require special disposal procedures. A summary of the use of RIAs to detect drugs of abuse in urine is presented in Table 8.

2.2.2 Enzyme-linked Immunosorbent Assay

ELISAs have been used in immunochemistry for a number of years. The absorbance, or binding, of an antibody or antigen to the wells of 96-well plates (or strips of plates) makes these assays amenable to rapid handling of up to 96 samples at a time – a number that can be readily multiplied, as the handling of more than one plate at a time is not problematic. ELISAs have been formulated in many different styles that can
Figure 5 A schematic of RIAs showing (a) an RIA that uses double antibody method to separate bound from unbound antigen, (b) an RIA that uses antibody-coated tubes to allow separation of bound from unbound antigen (e.g. DPC Coat-a-Count), and (c) a representative plot of signal versus drug concentration.

use secondary, and even tertiary, antibodies or other variations to amplify the reaction. The two types of ELISAs marketed for detection of drugs use a simple system. The antibody is bound to the well. Sample and horseradish peroxidase conjugated antigen compete for the binding sites. These are then rinsed out, and the bound enzyme is measured with the substrate 3,3',5,5'-tetramethylbenzidine (Figure 6). The enzymatic reaction forms a blue product that is measured at 630–650 nm. As recommended for the STC Diagnostics products, and offered as an option for the Diagnostix products, the reaction can be stopped by addition of 2 N sulfuric acid, which will convert the blue product to a yellow product monitored at 450 nm. As the amount of target drug in the sample increase, enzyme-conjugated antigen will be displaced and the resultant absorbance will decrease, as seen with the EIAs (Figure 2c). The assay requires a plate reader capable of monitoring the appropriate wavelengths. The assay can be facilitated with the use of a plate washer. The only published study of these ELISAs for urine drug testing is an evaluation of the STC Diagnostics method for the detection of LSD in urine. Further discussion of these methods will be presented in section 3.5 on other matrices.

2.3 On-site Drug Testing Immunoassays

Over the past few years, a number of companies have marketed “on-site” drug testing devices. Most of these kits utilize immunochromatographic techniques that allow the detection of a complex of membrane-adherent protein-conjugated antigen with antibody conjugated to a colored particle (e.g. colloidal gold, blue-dyed microparticles). With application of urine to a test strip, the target drug and conjugated antibody move up the strip by capillary motion (Figure 7a). Unbound antibody will bind to antigen at the viewing membrane. When no target drug is present, sufficient antibody binds at the viewing membrane to form a colored line (negative result, Figure 7b). When sufficient target drug is present, all the antibody will be bound and will not bind to the viewing window with no color formation (positive result, Figure 7c). Each strip also contains a control antibody that is specific for a control (nondrug) antigen adhered to a different section of the viewing membrane. This control reaction tests for appropriate functioning of the kit, and must form a colored line for acceptable results (Figure 7d).

Sample application to the kit may be done by dipping a strip(s) directly into the urine collection device, pipetting a portion of the urine into a test well or tilting a collection cup so that a portion of the urine flows into attached testing wells. Kits are configured to test from one to 10 drugs in a single device. Some kits also include a human urine test, where the same principle is used to detect human immunoglobulin G (IgG) in the sample (anti-human IgG is conjugated to the test antibody, and human IgG is adhered to the viewing membrane).

A number of the kits have now undergone rigorous evaluations comparing their results with those of laboratory-dependent immunoassays and GC/MS confirmation with fairly favorable results (Table 9). Their primary limitation may arise from the subjective nature of detecting a minor color difference between a sample that contains drug at concentrations just below, or just above, the cutoff. In part, this will be determined by

3 SAMPLE PREPARATION AND MATRIX FACTORS

3.1 Introduction

Most of the immunoassays used to detect drugs of abuse in forensic toxicology laboratories are formulated for use with urine samples. The analysis of physiological fluids, besides urine, and tissues for drugs and drug metabolites, however, is an essential component of forensic toxicology. Many immunoassays have therefore been evaluated for their use with these nonurine matrices. Three main factors must be considered in the use of urine-formulated immunoassays in analysis of other fluids and tissues. First, with the exception of most parenchymal organs with their rich blood supply, other fluids and tissues will have lower concentrations of the target drug than found in urine. Second, with the exception of other nonviscous fluids (e.g., vitreous humor, cerebrospinal fluid), the matrix has to be converted into a more soluble form for analysis. Third, the analyte targeted by the urine-formulated immunoassay may not be the metabolite (or parent drug) that is present in that particular matrix at the highest concentration. Many strategies have been devised to deal with these issues. Those used for analysis of blood and hair will be addressed in some detail. Issues pertaining to the immunoanalysis of other tissues and fluids, including urine, will also be addressed.

3.2 Urine

Urine is the most common matrix used for forensic drug testing. While some issues of privacy occur with urine collection, it is still a noninvasive mode of sampling and relatively large volumes can be readily collected. Furthermore, urinary excretion of most drugs, or their metabolites, leads to an accumulation of the analyte in the bladder; concentrations of drugs and/or drug metabolites in urine are relatively high. Aliquots of urine are commonly used without any prior sample preparation. A common exception is the need to centrifuge particularly turbid specimens prior to analysis by assays that use spectrometric detection methods. Another key exception to this rule is immunoassay screening for benzodiazepines. As first demonstrated by Beck et al.\(^{(44,107)}\) and subsequently substantiated by others,\(^{[60,108,109]}\) enzymatic hydrolysis of urine samples will increase the immunoassay detection of many benzodiazepines.

3.3 Blood

Blood, or the blood fractions serum and plasma, has traditionally been the favored sample for drug testing that is conducted to assess potential impairment or intoxication by the drug. Much more is known about correlation between blood concentrations of the drug or active metabolite with pharmacodynamic functions than with any other matrix. Two main issues have to be considered when transferring technology formulated for urine drug testing to blood drug testing. The first, is that most drugs and drug metabolites will be present in blood at much lower concentrations than found in urine. Second, blood contains cellular material (either whole or fragmented in hemolyzed blood) at much higher concentrations than found in urine. Attempts to use blood in urine immunoassays have had to develop procedures to enhance the sensitivity of the assay (or accept the limitations of sensitivity of the assay in regards to the matrix), and to transform the matrix to an acceptable form for analysis (Table 10).

The RIA has been applied to blood analysis with the fewest modifications. With the exception of analysis for cannabinoids, blood can be directly analyzed by RIA.\(^{[92,116]}\) Changes in sample and reagent volumes have been added to enhance sensitivity.\(^{[91,113,128]}\) Extractions of blood for RIA analysis have also been proposed when the sample was being analyzed using a robotic system\(^{[124]}\) and to enhance the sensitivity for benzodiazepines.\(^{[128]}\) Cannabinoid detection by RIA has required a simple methanolic deproteinization;\(^{[90]}\) blank whole blood itself has too much variation in signal to allow proper calibration.\(^{[123]}\)

Like RIAs, ELISAs are heterogeneous immunoassays. Theoretically, matrix differences will also have less impact on ELISAs used for drug testing. These assays are new to the drug testing field, however, and only a few studies have been published on their use. Those now available show that ELISA has promise for testing of whole blood with little or no modification. Methanolic deproteinization was used by Perrigo and Joynt to study a number of drugs.\(^{[127]}\) Cassells et al.\(^{[93]}\) were able to use whole blood directly to detect LSD in LSD-fortified blood samples and Spiehler et al.\(^{[131]}\) diluted blood samples 1:2 with buffer to facilitate ELISA detection of a number of drugs.

Analysis of blood with EMIT, CEDIA and TDx homogeneous immunoassays has always required, at the

least, deproteinization or more thorough extractions with reconstitution (Table 10). Simple deproteinizations that can be followed by centrifugation and direct analysis of the supernatant (sometimes after frozen storage) have been reported using methanol, N,N-dimethylformamide, zinc sulfate in methanol and sodium sulfate in acetonitrile. Yee et al. reported a simple modification of these simple deproteinizations where blood was mixed with phosphate buffer–methanol (80:20) and centrifuged in a filtering tube, so the filtrate could be used. Extractions with reconstitutions have ranged from simply adding acetone or butyl chloride, drying the organic phase and reconstituting, to more elaborate extraction schemes. The more elaborate extractions will recover and concentrate more of the drug, but they can be much more time-consuming.

Serum has less protein and other cellular material than whole blood, and many automated homogeneous immunoassays have been developed for the direct measurement of therapeutic drugs in serum. As serum is the most common matrix collected in emergency room settings, there is often a need to use serum for drugs of abuse testing. Applying immunoassays developed for urine drug testing to serum samples, however, still has to deal with the lower concentrations of drug found in this matrix. Examples of assay of serum samples follow.

Poklis et al. found that they could measure serum directly for benzoylcegonine with EMIT d.a.u. reagents on an ETS® using calibrators modified to a lower cutoff of 50 ng mL⁻¹. At this cutoff, positive versus negative results in serum matched the results of urine samples screened at a 300 ng mL⁻¹ cutoff. GC/MS of the 45 positive sera with a cutoff of 50 ng mL⁻¹ was only positive for 67%, but benzoylcegonine was detected in half the volume of 0.1 M potassium phosphate (pH 7.4) to detect cannabinoids, benzoylcegonine and morphine using OnLine KIMS reagents on a Cobas Mira. They found that extraction was necessary to detect the target drugs at concentrations anticipated in serum. Furthermore, extraction provided greater precision of analysis. Iwersen-Bergmann and Schmoldt used the same acetone deproteinization–extraction with reconstitution in ADx buffer as applied to whole blood to detect cannabinoids, benzoylcegonine, opiates, benzodiazepines and methadone successfully using CEDIA d.a.u. reagents on a Hitachi 911 instrument with the same settings as used for urine. It was found that further modifications would be required to detect amphetamines.

### 3.4 Hair

Hair is an important and accessible matrix for the detection of exposure to drugs. One of the more unique features of hair testing is the preservation of the evidence of exposure for periods of time approximately proportional to the length of the hair. Ongoing controversies about the use of hair as a matrix for workplace drug testing exist. These include the potential for external contamination and amassing evidence that basic drugs accumulate in darker hair to a greater extent because of drug binding to melanin. Hair is, however, a well-studied matrix, that with proper allowances for extenuating circumstances can be used for forensic drug testing.

Hair cannot be measured for drugs of abuse directly by immunoassay. A number of thorough reviews of techniques to prepare hair for both immunoassay and chromatographic assays have been published. Representative studies in which hair extracts were analyzed by immunoassay are presented in Table 11. The hair sampling should avoid inclusion of the hair follicle, as this will include some blood and other tissue. Whether hair is further segmented by length to assess approximate time intervals is optional, but should be noted. The hair sample usually goes through a rinsing/washing step followed by an extraction/digestion of the hair. A number of different washing techniques have been employed that included dilute detergents, surfactants and weak solvents (Table 11). Methanolic extraction was used in initial studies and has continued to be used in some laboratories. Most laboratories, however, have employed extraction methods that essentially digest the hair protein matrix. These have included digestions in strong acid (HCl) or base (NaOH) and proteolytic digestions (Table 11). The first two methods require neutralization of the digest before it can be used with an immunoassay. Although proteolytic digestion was initially introduced in 1989 by Offidani et al., it has only recently become more widely used. It is recommended when unstable compounds are to be detected. Supercritical fluid extraction of rinsed hair has also been used to prepare extracts for immunoassay.

RIA has been used almost exclusively for the detection of abused drugs in hair (Table 11). RIAs are generally more sensitive, which permits the detection of the low concentrations of drug or drug metabolites that are present in hair. In addition, because RIAs are heterogeneous immunoassays, they are probably less susceptible to interference from residues of the hair processing methods. Franceschin et al. and Kintz et al. have reported the use of TDx FPIAs to detect drugs in hair. Whereas Franceschin et al. and Lewis et al. required a more extensive extraction technique, Kintz et al. reported that a number of different drugs could...

</tbody>
</table>
be detected following a more routine extraction of the hair. At this time no other laboratories have reported the use of this assay for hair analysis. The new STC Diagnostics ELISAs for cocaine appear to provide sufficient sensitivity for hair screening; a current study in our Center has used this approach with GC/MS confirmation (D.G. Wilkins, personal communication). While RIAs will continue to play a major role in the immunoassay detection of drugs of abuse in hair, further research will probably find roles for other immunoassays.

While some of the larger commercial laboratories used immunoassay screening of hair on a routine basis, a great deal of research on the preparation of hair for drug testing has relied solely on chromatographic techniques for drug measurement. As this review has focused on the application of immunoassay techniques for drug measurement, many are referenced in the reviews on hair preparation techniques. Many are referenced in the reviews on hair preparation. (136, 143–146)

3.5 Other Matrices

A number of other tissues and physiological fluids have been studied as matrices for the detection of drugs of abuse (Table 12). Three that have been examined extensively are saliva, meconium and sweat. Saliva can be collected in a noninvasive manner, and therefore has been advocated as an alternative to blood for drug testing. Concentrations of some drugs are present in saliva at concentrations close to those in blood. Many factors affect the secretion of drug and drug metabolites into saliva, pKₐ and plasma protein binding being two of the most important. As salivary pH is variable, it usually differs from that of blood, and this difference appears to have the greatest impact on blood to saliva ratios of drugs with pKₐ values <6 or >8. These variations can have an impact on interpretation of saliva drug concentrations, when most of the pharmacodynamic studies are based upon correlates to blood concentrations. A number of immunoassay approaches to detecting drugs in saliva have been reported (Table 12).

Meconium has been widely used in studies on the exposure of the fetus to drugs from drug use during pregnancy. As the initial fecal excretion of a newborn, meconium can be collected in the diaper(s) over 24–36 h after birth, and provides an accumulative record of drugs that circulated in the amniotic fluid during the latter stages of gestation. As an accumulative

*See Table 1 for number assignment to drug groups.*

record, meconium measurements do not pinpoint times of exposure. The analytes present in meconium are a product of both maternal and fetal metabolism. Some metabolites rarely seen are found in meconium, probably because of unique fetal metabolic pathways. A number of studies have addressed the use of immunoassays to detect drugs of abuse in meconium homogenates or extracts of meconium homogenates.

Sweat is another physiological fluid that is gaining popularity as a matrix for drug testing. The presence of drugs in sweat has been known for many years. The use of this fluid has lately become more popular as collection patches have been developed that permit the evaporation of water and other small molecules. This alleviates the irritation that was common with older methods of collection and precluded sampling for more than a day or two. Patches can now be applied for 1–2 weeks, and are therefore advocated for testing programs where long-term monitoring is important, such as for patients in drug treatment programs and parolees. Immunoassays, particularly RIA and more recently ELISA, have been used to detect drugs of abuse in sweat (Table 12).

Several other matrices have been reported as useful for the detection of abused drugs and other drugs of interest to the forensic toxicologist (Table 12). The use of a particular matrix depends upon the situation at hand (e.g. stains or dried blood spots), limitations of other matrix availability and the specific population to be studied. If the technology applied is sensitive enough, a drug or drug metabolite may be found in the matrix. Immunoassays occasionally provide the sensitivity for this purpose (Table 12).

4 FORENSIC APPLICATIONS

4.1 Detection Limits and Cutoffs

The sensitivity of an immunoassay is commonly defined from the signal generated by a blank matrix. The usual experiment would analyze a number (e.g. 20) of replicate
blank matrix samples and determine the mean and standard deviation (SD) of the blanks. The concentration that is equivalent to the blank signal ±3SD would be established as the limit of detection (LOD).

The lower limit of quantitation (LLOQ) and upper limit of quantitation (ULOQ) should be established if the immunoassay is to be used in a quantitative manner. The LLOQ can be defined in a manner similar to the LOD, in this case using the blank signal ±10SD. It is becoming common practice, however, to define both upper and lower limits from actual replicate measurements of test calibrators, and accepting the limits when precision and accuracy are within certain limits (e.g. 15–20%).

Cutoffs are used in many testing procedures to establish strict guidelines as to whether the result of an immunoassay screen will result in further confirmational testing, or in screening-only programs a positive test result. In those programs, cutoffs are also used for confirmations to dictate a concentration that will trigger a positive report. Cutoffs do not always reflect the LOD of a particular immunoassay. For example, 300 ng mL\(^{-1}\) is a commonly used cutoff for methadone detection. Stated LODs of immunoassays for methadone range from 0.02 to 20 ng mL\(^{-1}\) (Table 13). EIA reagent manufacturers rarely state a sensitivity for their assay, in part because they are formulated for many different instruments and sensitivity can be instrument dependent (Table 13).

Testing programs, such as medical examiner’s offices, that are interested in the detection of any drug present will often establish cutoffs based upon analytical sensitivity. Not only must the LOD of the immunoassay be considered, but also the LOD or LLOQ of the confirmational assay must be considered. It is worthless to establish a screening cutoff that is lower than the confirmational LOD or LLOQ. Legal challenge is another factor to be considered in establishing the screening cutoff. Two well-known examples involve cannabinoids and opiates.

Most immunoassay methods were initially designed and had sufficient sensitivity to screen for cannabinoids at 20 ng mL\(^{-1}\) with few false-positive screens. However, passive inhalation of marijuana smoke (under potentially extreme conditions) was found to result in some urines that screened positive at the 20 ng mL\(^{-1}\) cutoff, but few or none at the 100 ng mL\(^{-1}\) cutoff. Therefore, when cutoffs for federal urine drug testing programs were initially established, the potential for a “passive inhalation” defense played a role in setting the cannabinoid screen cutoff at 100 ng mL\(^{-1}\). With experience, it became evident that many cannabinoid users were being missed with the 100 ng mL\(^{-1}\) cutoff and, along with other factors, that passive exposure would not surpass a 50 ng mL\(^{-1}\) cutoff. The cannabinoid screen cutoff was lowered to 50 ng mL\(^{-1}\).

Poppy seeds are legally used in many food products. They contain opiates, including morphine and codeine, or compounds metabolized to morphine and codeine. It has long been known that ingestion of foodstuffs containing sufficient amounts of poppy seeds can result in a confirmed positive screen for opiates, particularly at the commonly employed cutoff of 300 ng mL\(^{-1}\). The “poppy seed” defense for an opiate positive urine drug test often overturned a positive finding. Other factors were also having an impact on the use of a 300 ng mL\(^{-1}\) cutoff for opiates. Prescription use of codeine was causing a number of positives. While the licit nature of these positives would eventually be unraveled, it required a great deal of energy from the medical review officers and laboratory directors. To counter these and other factors, the screening cutoff for opiates has been increased to 2000 ng mL\(^{-1}\) in many drug testing programs. In addition, to focus on positive illicit opiate use, confirmations must also include the detection of 6-monoacetylmorphine, a metabolite unique to heroin.

Other licit foodstuffs and drugs may cause similar problems if either an incomplete history is available or if the immunoassay test result is the sole finding. Examples of foodstuffs include hemp seed oil and coca tea consumption. Selegiline is metabolized to \(l\)-amphetamine and \(l\)-methamphetamine; some inhaler cold remedies contain \(l\)-amphetamine. Use of either of these in sufficient doses can result in urine concentrations that trigger a positive immunoassay test in assays that do not have specificity for the \(d\)-isomer. A chiral chromatographic confirmation is then required to discriminate these from \(d\)-amphetamine and \(d\)-methamphetamine. Such a confirmation is now used by many laboratories.

The establishment of the cutoff can be mandated by law, or determined by negotiation between the laboratory and its client. Examples of some federally mandated cutoffs for pre-employment and random urine drug testing are given in Table 14. Railroad employees will be routinely tested for drugs in urine under DOT guidelines. The Federal Railroad Administration, a component of the DOT, also operates a mandatory postaccident drug testing program. This program will screen for drugs.

\(^b\)Confirmation of \(d\)- and \(l\)-isomers required.

\(^c\)While the current mandated cannabinoid screening cutoff is 100 ng mL\(^{-1}\), an interim cutoff of 50 ng mL\(^{-1}\) has been implemented until it is officially approved. Both cutoffs are used, the 50 ng mL\(^{-1}\) to determine which samples go on to confirmation and the 100 ng mL\(^{-1}\) for summary reports (D. Kuntz, NWT Inc., personal communication).

in urine with confirmation in urine and blood. The cutoffs employed by this program (Table 15) illustrate the focus of this program in determining drug involvement in the accident, rather than just prior use of drugs.

4.2 Cross-reactivities

Antibody detection of an analyte is fairly selective, but not perfect. Immunoassays designed for a specific drug (e.g. methadone) will detect other compounds. The extent to which they do that is called the cross-reactivity of the antibody. Cross-reactivity is usually found for analogs and metabolites of the primary analyte. Amphetamines, opiates, barbiturates and benzodiazepines each have a number of over-the-counter (amphetamines) and prescription analogs within their drug class. Many of these will be detected by the respective immunoassay. Depending upon the purpose of the immunoassay, this can be beneficial or a hindrance. In the medical examiner laboratory, this is beneficial. In the workplace setting, where only restricted drugs can be confirmed positive, it is often a hindrance.

With amphetamines, the drugs \(d\)-amphetamine and \(d\)-methamphetamine, and in some drug-testing programs, the illicit designer amphetamines MDA, MDMA and MDEA, are confirmed after positive immunoassay screens. When positive screens are caused by over-the-counter amphetamines such as phenylpropanolamine, this is a hindrance to the workplace drug-testing process, and accounts for some of the false-positive screens. A similar situation exists for the opiates. Many drug-testing programs (e.g. SAMHSA) are primarily interested in the detection of illicit heroin use. For this purpose, confirmations are now for morphine and 6-monoacetylmorphine (metabolites of heroin), and codeine (to rule out another source of morphine). There are, however, many other prescription opiates, such as hydrocodone, hydromorphone, oxycodone and oxymorphone, that will cross-react to a certain extent with many immunoassays. The detection of most of these drugs, including the over-the-counter amphetamines when at toxic doses, is important in most other toxicology laboratories.

For benzodiazepines and barbiturates, the cross-reactivity is usually within the drug group for the large number of analogs available on the prescribed drug market. When these drugs are part of the drug screen, the

</table>

\(^a\) Urine is normally the only specimen screened (KIMS); blood is only screened (RIA) if urine is not available; both blood and urine are confirmed if urine screens positive.

\(^b\) A confirmed urine positive for amphetamine or methamphetamine will result in a \(d\)- and \(l\)-isomer analysis and is reported as the percentage of each isomer present.

\(^c\) Urine benzodiazepine concentrations are reported if above the LLOQ and only if the blood concentrations (of same drug or parent drug) are above the cutoff. If a blood specimen is not received and the urine concentration is above the LLOQ, then the urine specimen may be reported.

\(^d\) The blood specimen (or urine if blood is not available) is analyzed for ethanol by gas chromatography (GC). If the blood is positive, the analysis is repeated using a separate portion of the specimen and urine is also analyzed by GC.

difficulty is in the extensive number of drugs that must be considered during confirmation assays. Additional problems occur for benzodiazepines. The antibody used in most immunoassays is directed towards oxazepam or nordiazepam that are themselves first-generation benzodiazepines, or are metabolites of many other first-generation benzodiazepines.\(^{129}\) Some of the newer benzodiazepines differ in structure sufficiently such that there is only poor cross-reactivity. This is particularly true for the nitrosobenzodiazepines such as clonazepam and flunitrazepam, and structurally diverse benzodiazepines such as mexazolam and haloxazolam\(^{129}\). In addition, the newer generations are more potent and have resultant lower urine and blood concentrations than the first-generation benzodiazepines.\(^{222}\) This compounds the problem of detecting the benzodiazepines with poor cross-reactivity in urine. In blood, the low concentrations can even impede detection of benzodiazepines with relatively good cross-reactivity such as alprazolam and triazolam. Immunoassay detection of some benzodiazepines remains a challenge.

Occasionally, an antibody will be cross-reactive with a drug from a different drug class. These include
oxaprozin with benzodiazepine immunoassays\cite{223,224} and phenytoin and its metabolite with the TDx FPIA for barbiturates\cite{225}. As these drugs will rarely be on the respective confirmation list, those false-positive screens are rarely explained.

Many assays will also detect closely related metabolites. As the metabolites will be present in the same urine sample, sometimes in higher concentrations than the target drug, cross-reactivity for the metabolite will contribute to the signal generated by the immunoassay. This is often the case for cannabinoids and is the main reason that the immunoassay cutoff is usually much higher than the GC/MS cutoff.

A representative list of studies on the cross-reactivity of commercial immunoassays for analogs and metabolites is given in Table 16. These studies are best used to see how structurally related compounds can be detected by immunoassays and for methodologies of conducting cross-reactivity studies. The antibodies used in commercial kits will change over time. Therefore, the most up-to-date, albeit often limited, cross-reactivity data is that present in the package insert.

An example of the effect of analog and metabolite cross-reactivity can be seen with the use of methadone (1) immunoassay kits for the detection of $l$-$\alpha$-acetylmethadol (LAAM) (2). LAAM is a longer acting analog of methadone recently approved as an alternative for maintenance therapy of opioid-dependent subjects\cite{240}. LAAM is successively N-demethylated to norLAAM (3).

and dinorLAAM (4) and all three compounds are pharmacodynamically active. The structural similarity of methadone, LAAM, norLAAM and dinorLAAM can be seen from the formulas shown. To determine the cross-reactivity of LAAM, norLAAM and dinorLAAM, the compounds were prepared separately in drug-free urine at concentrations ranging from 30 to 100 000 ng mL\(^{-1}\) and analyzed using the OnLine KIMS immunoassay, the DPC RIA and the TDx FPIA (Figure 8a–c). Cross-reactivity for LAAM was RIA > KIMS > FPIA. Cross-reactivity for the LAAM metabolites decreased with each N-demethylation (Figure 8a–c). These data suggest that these kits will detect LAAM in urine samples and that methadone immunoassays will not discriminate people who are taking methadone from those taking LAAM.

### 4.3 Interfering Substances

Particularly in workplace drug testing, an ongoing battle has been occurring to try to interfere with positive urine drug tests. A whole host of common household items or commercially available interferents have been used to alter submitted urines. As seen for cannabinoid immunoassays, many of these interferents will cause positive urines to test negative. Some, however, will cause negative urines to screen positive (Table 17). Many of these substances will be detected with the use of common adulterant tests that include pH, specific gravity, smell and appearance.\(^{(241,243,344,246)}\) A notable exception is Visine eyedrops.

Many other substances have been reported to interfere with immunoassays for drugs of abuse. Nonsteroidal anti-inflammatory drugs have been found to interfere with some EMIT and TDx FPIA assays, but to varying degrees.\(^{(251–253)}\) Addition of excess antibody reagent to the EMIT cocaine metabolite assay resulted in false-negative screens.\(^{(254)}\) False-positive EMIT results have been seen in postmortem urine from subjects with both proteinuria and lactic aciduria,\(^{(255)}\) as the presence of both the lactate dehydrogenase and its substrate leads to conversion of NAD to NADH. Denture-cleaning tablets were found to reduce the results of TDx FPIA analysis for amphetamines, benzoylecgonine and THC.\(^{(256)}\)

Although nitrites have not been studied much for their effect on immunoassays, they should also be mentioned as they are a common adulterant that appear to act by degrading THC. Urines containing high concentrations will screen positive, but in the short time required to go to confirmation the THC will have decreased sufficiently to not be confirmed.\(^{(257)}\)

Concentrations of nitrites that exceed those associated with disease states or therapy have been established and methods to determine nitrite concentrations have been published.\(^{(258–260)}\) The test-strip method also tests for glutaraldehyde, which is the other most common adulterant used at this time. As the battle continues, we can be assured that new adulterants will enter the picture.

### 4.4 Interpretation of Results (Need for Confirmation and Quantitative Versus Qualitative)

All commercial immunoassays have a statement in their package insert that says the assay is only an initial test and all positive results should be confirmed with a second test, GC/MS being currently recommended. The preceding portions of this section should offer the rationale for this statement. An immunoassay screen is quick, but confirmations are not. This often leads to situations, such as the emergency room or the admittance of workers to dangerous workplace settings, where action is taken based upon the result of an immunoassay itself.

\(^{a}\) NE, no effect; FN, false negative, caused urine fortified above cutoff to test below the cutoff; FP, false positive, caused urine with no drug present to test above the cutoff. Consult the specific reference to find concentrations of adulterants used that gave indicated result. In general, liquid adulterants were not studied at concentrations in excess of 10% (v/v).

This is considered an acceptable practice. For further consequences (e.g. termination of employment), resting upon the immunoassay result alone is not an acceptable practice. The value of the immunoassay in the forensic laboratory is as a screen. It provides a yes/no answer to the question of whether further testing is required. When a confirmed positive result arises, it provides evidence for qualitative detection by a second unique methodology.

Immunoassays provide concentration-dependent signals. What is the quantitative value of the immunoassay? As discussed under cross-reactivity, however, these signals can result from the detection of more than one analyte. An example of the selectivity of the immunoassay is given in Figure 9(a) and (b). Marijuana contains a number of cannabinoids that will appear in the urine after smoking or oral ingestion. While commercial immunoassays are designed to detect THCA, many of these cannabinoids are recognized by immunoassays. When a number of urine samples were measured by Abuscreen immunoassay in a quantitative mode and for THCA by GC/MS, a very poor correlation was found between the two assays (Figure 9a). Cocaine is metabolized predominantly to benzoylecgonine and eegonine methyl ester. As eegonic methyl ester results from hydrolysis of a bulky benzyol group, it loses much of its structural identity to benzoylecgonine and is general poorly recognized by immunoassays designed to detect benzoylecgonine. The consequence of this is that cocaine metabolite immunoassays designed to detect benzoylecgonine are fairly specific (Figure 9b).

Two approaches to the use of immunoassay results have been taken. One, more commonly used in the forensic laboratory setting, is the determination of the need for confirmation on a diluted sample and setting the order of samples in a GC/MS batch to diminish carryover. In this manner, a sample with a high immunoassay result may be prepared using a full aliquot and a diluted (e.g. 1 : 10) aliquot, and nondiluted aliquots with high readings being grouped together in a GC/MS batch. This can save time and the need to repeat samples.

Quantitative immunoassays have been used in a number of pharmacokinetic studies. These must be interpreted carefully and with knowledge of the cross-reactivity of the antibody for metabolites of the primary analyte. In substance abuse treatment programs, the use of quantitative measurements to monitor increases and decreases in drug use has been proposed as a better measure of the efficacy of treatment.\(^{(261,262)}\) This requires assays with relatively good selectivity for the analyte in question, as can be achieved with mass spectrometric...
methods of analysis for most drugs or drug metabolites. This is also the case for immunoassays designed for the detection of cocaine metabolite in urine. Indeed, the accuracy and precision of immunoassays for the semiquantitative detection of benzoylecgonine (BE) have been demonstrated.\(^\text{(263–265)}\)

Immunoassays have provided a powerful tool for the forensic toxicologist to screen large numbers of specimens for the presence of certain drug classes. When combined with a selective confirmational method such as GC/MS or LC/MS, they have become indispensable in the current laboratory setting. Immunoassays do, however, have limitations. They detect other analytes than the primary analyte, and they are subject to certain interferences. Furthermore, some drugs in the drug-class of an immunoassay may not have sufficient cross-reactivity at the concentration present in the sample to be detected (e.g. the potent benzodiazepines, some opiates). Interpretation of the immunoassay result must consider these limitations, particularly if the immunoassay result is used by itself or in a quantitative manner.

**ACKNOWLEDGMENTS**

Much of my education in the use of immunoassays must be attributed to my fellow directors at the Center for Human Toxicology, Douglas Rollins, Rodger Foltz, Dennis Crouch, Diana Wilkins and David Andrenyak. I must also acknowledge the input I have received from several colleagues at meetings that include the Society of Forensic Toxicologists, the California Association of Toxicologists and the International Association of Forensic Toxicologists. For any knowledge I impart with this article I thank them. Mistakes and misinterpretations are solely my responsibility. Supported in part by USPHS grant RO1DA 10100 and contract NO1DA-7-8074.

1 INTRODUCTION AND HISTORY

The ion mobility spectrometer (IMS) is a device used primarily for detection, identification, and monitoring of trace amounts of gases or vapors. Generally, sample introduction, ionization, ion separation, and detection all take place at ambient pressure, so that elaborate vacuum systems are not required. IMSs are typically small (portable, hand-held or even pocket-sized) and respond within seconds to part per billion (ppb), or even part per trillion (ppt) concentration levels. The IMS is not a universal detector and is not suitable for all compounds. It has a limited dynamic range due to its finite reservoir of charge, and may suffer from matrix effects which could interfere with the ionization or ion separation processes and cause spectral interferences. These drawbacks have limited the application of IMS technology to a few fields that require high sensitivity and rapid response, such as the detection of chemical warfare agents (CWA), explosives, and illicit drugs, and the identification and monitoring of toxic gases or vapors.

The array of field and laboratory instruments available today have become useful tools in the prevention of illicit use of contraband substances and in the rapid identification of these and other toxic substances. This article describes the principle of operation of IMS and the basic gas-phase ion chemistry underlying the technology. The proven experience, both in the field and in the laboratory, of IMSs for forensic science applications is also described, and the merits and shortcomings of present-day IMS technology, and future trends, are discussed.

1 INTRODUCTION AND HISTORY

The IMS device is used primarily for detection, identification and monitoring of trace amounts of gases or vapors. Its high sensitivity arises from the fact that the atmospheric pressure ionization (API) processes, that occur in the source region, efficiently transfer charge to the analyte molecules present in trace amounts in the sample and produce ions that are typical of the analyte. IMSs are particularly suitable for detection of compounds that have a high proton affinity (PA) and form stable positive ions, or for compounds that have a high electronegativity (EN) and readily form stable negative ions.

Almost since its advent in the early 1970s, the potential of plasma chromatography, as ion mobility spectrometry was then called, for forensic applications was realized by its inventors. Indeed, the first report on the technique deals with detection of personnel...

1/ and other early reports explored detection of explosives as well as narcotics. However, as with other promising techniques, time was needed for the technology to mature, and for the array of field and laboratory instruments now available to become useful tools in the prevention of illicit use of contraband substances and in the rapid identification of these and other toxic substances. The
modern IMS contains the following basic features: a sampling and sample introduction system, an ionization source, a device to separate ions according to their mobility and to detect them and, finally, a signal-processing capability to derive the desired information, as shown in Figure 1.

A rather loose definition of forensic sciences is used throughout this article. In addition to the classical areas of detection of concealed explosives and illicit drugs, IMSs have been used to identify residues of explosives on suspects or in post-detonation debris, or illicit drugs and abuse of prescription drugs in clinical samples and on objects, IMSs have also found applications in identification of arson materials and tear-gas residues. Nerve agents, which after being used in a terrorist attack in a train station in Japan, and other highly toxic chemicals and biological materials, may now be part of a terrorist’s arsenal and are no longer confined to the military battlefield.

To date, only two monographs devoted solely to IMSs have been published.\(^5\)\(^6\) Several review articles have been published in English,\(^7\)\(^–\)\(^12\) but only one was dedicated to forensic applications of the technique,\(^12\) and recently a review of explosive detection by IMSs appeared as a chapter in a book on explosives.\(^11\) A two-part comprehensive review on forensic applications of IMSs, authored by forensic experts, appeared recently in German.\(^13\)\(^14\) Since the last review paper in English appeared progress has been made in this particular field, and the most rapidly growing commercial applications of IMS technology are in areas which may be categorized as forensic sciences.

The fact that most of the work reviewed here was published by instrument manufacturers and by law-enforcement agents that describe actual field experience with IMSs is indicative of the maturity of the technology.

1.1 Principle of Operation

The IMS utilizes the fact that a mixture of different ions may be separated into individual components as they travel at different velocities (mobilities) under the influence of an electric field through a tube containing a drift gas. The IMS may also be, somewhat naively, viewed as a variation on some more familiar techniques. On the one hand, it can be compared to the time-of-flight (TOF) mass spectrometer operating at an elevated pressure (usually ambient) with a very short flight (or drift) tube. On the other hand, the IMS may be compared to a gas chromatography (GC) apparatus with a virtual column (drift gas) as the stationary phase and may even be regarded as gas-phase electrophoresis device where the drift gas replaces the liquid.

The principles that govern the ionization and ion formation processes in the IMS are quite similar to those that dominate API and chemical ionization (CI) mass spectrometry (MS). The more specific gas-phase ion chemistry and ion–molecule reactions that pertain to explosives, drugs, and the other substances discussed in this article are reviewed in the relevant sections.

1.2 Mobility and Reduced Mobility

A comprehensive and detailed discussion of mobility theory, as it relates to ion mobility spectrometry, i.e. under conditions of “low-field”, may be found in the fundamental paper by Revercomb and Mason\(^15\) and in the two monographs mentioned above.\(^5\)\(^6\) This section presents only a brief and basic explanation of mobility and reduced mobility that pertain to the IMS in practice.

When an ion moves under the influence of an electric field, through a bath gas, its drift velocity \(v_{\text{d}}\) is proportional to the strength of the field \(E\) (Equation 1):

\[
v_{\text{d}} = KE
\]

where the proportionality constant \(K\) represents the mobility of the ion. If the drift velocity \(v_{\text{d}}\) is substituted with the quotient \(d/t\), where \(d\) is the distance the ion traverses in time \(t\) and Equation (1) is rearranged, the expression for the mobility becomes (Equation 2)

\[
K = \frac{d}{Et}
\]

When \(d\) is given in centimeters, \(E\) in volts per centimeter and \(t\) in seconds, the units of the mobility constant are \(\text{cm}^2\text{V}^{-1}\text{s}^{-1}\). However, as the ambient conditions of temperature \(T\) and pressure \(P\) that directly affect the ion velocity may vary from one location to the next and between instruments, it is common practice to normalize these values to standard temperature (273 K) and pressure (760 torr) conditions and use the “reduced

---

**Figure 1** Block diagram of a generic IMS. Note the two major sections of the drift tube: the ionization (or source) region where ions are formed and the drift region where they are separated according to their mobilities.
mobility’’ $K_o$. This is a universal characterization of the ion, according to Equation (3):

$$K_o = \frac{d}{Et} \frac{273}{T} \frac{P}{760}$$  \hspace{1cm} (3)

where $T$ is expressed in degrees Kelvin and $P$ in torr. The units of the reduced mobility are also cm² V⁻¹ s⁻¹.

When two ions, $i$ and $j$, with different mobilities are formed and they drift along the same IMS tube, i.e. the same electric field, temperature and pressure affect both ions as they traverse the same distance, only the time it takes them to travel this length, $t_i$ and $t_j$, would differ. As seen from Equation (3), the ratio between the drift times of these ions, $t_j/t_i$, would be inversely proportional to the reduced mobility ratio:

$$\frac{K_{io}}{K_{jo}} = \frac{t_i}{t_j}$$  \hspace{1cm} (4)

Equation (4) actually represents a functional approximation of the reduced mobility, which is widely used by practitioners of IMS technology. Usually, $i$ would be an ion from a reference compound with a known reduced mobility and $j$ the ion (or ions) derived from the analyte. It should be noted that none of the above equations include any information on the ion itself: its polarity, charge, mass, shape, internal charge distribution or structure. Nor is there any reference to the type of gas through which the ion drifts. The term for the mobility (or reduced mobility) should contain this information and reflect how all these parameters affect the motion of the ion. According to low-field mobility theory, the mobility of an ion may be expressed in Equation (5) as:

$$K = \frac{3e}{16N} \left( \frac{2\pi}{\mu kT_{eff}} \right)^{1/2} \frac{1 + \alpha}{\Omega_D(T_{eff})}$$  \hspace{1cm} (5)

where $e$ is the ion charge, $N$ is the density of the drift gas molecules, $\mu$ is the reduced mass of the ion–neutral collision pair $[mM/(m + M)]$ (where $m$ is the ion mass and $M$ is the mass of the drift gas molecules), $k$ is the Boltzmann constant and $T_{eff}$ the effective temperature of the ions. The parameter $\alpha$ is a correction factor (usually below 0.02 for $m > M$) and $\Omega_D(T_{eff})$ is the collision cross-section which depends on the effective ion temperature. This latter term represents the interactions between the ion and drift gas molecules, which depend on the ion size, shape, charge distribution, and the nature of the drift gas.

### 1.3 History

A detailed history of the evolution of modern ion mobility spectrometry is available. In brief, ideas that originated at the turn of the twentieth century, and further developed half a century later, reached maturity and were presented in the form of a practical instrument in the late 1960s. A considerable boost to the new technique was given by Karasek and co-workers who published an impressive array of articles that outlined the potential of the technology for solving practical problems, particularly for explosives and narcotics detection. It is noteworthy that the first publication involving an IMS dealt with a forensic application: the marking and detection of personnel. The potential for forensic applications, mainly detection and identification of explosives and drugs, is still one of the main driving forces of ongoing IMS development as reflected by the numerous papers presented at the annual IMS workshops and by the number of commercial manufacturers of IMSs.

### 2 INSTRUMENT DESIGN

A block diagram of the main components of the IMS is shown in Figure 1, and Figure 2 is a diagram of a commercial IMS (the Ionscan by Barringer). As can be seen in the photographs of IMSs in the following sections, the actual design may vary considerably from one instrument to the other. However, all IMSs must have a means of introducing the sample and of creating ions from vapors that emanate from the sample. The drift tube is the key component of the IMS, as this is where ions are separated according to their mobilities. Finally, a detector measures the ion current, the signal is processed, and the results are displayed according to the requirements of the particular application.

This basic scheme may be modified, as necessary. In the following sections the common designs for these components are described. It should be borne in mind that for most forensic applications the instrument should be able to detect and identify the substances of interest and provide the operator with “hit” results if contraband substances are found. This requires, first and foremost, a means of bringing the target analyte molecules to the IMS and introducing sufficient vapor into the drift tube to enable sensitive detection and true identification. Furthermore, identification of the target compound may be based on an algorithm for signal processing that uses a reference compound for calibration of the mobility scale; thus the results may only be displayed as a tabulated list, or the whole spectrum may be shown so that the operator has to make a judgment as to whether a target analyte was detected.

Most ionization sources produce both positive and negative ions. By selecting the direction of the electric field gradient in the source and along the drift tube, the polarity of ions that are detected may be chosen. Some IMSs are capable of measuring both polarities simultaneously (with two drift tubes) or sequentially (by periodically switching
between the two polarities). The polarity of choice would depend on the application – generally negative polarity for explosive detection and positive polarity for drugs.

2.1 Sampling and Sample Introduction

For several applications, such as monitoring the concentration of vapors in air or for identification of a substance absorbed on a sample holder, a simple system for drawing ambient air into the instrument is quite suitable. However, detection of hidden contraband material requires special sampling techniques, in order to gather enough material from which to produce ions that will allow the unequivocal detection and identification of the target analytes. Some of these substances have exceptionally low vapor pressures, so that straightforward vapor-sniffing techniques would not be sensitive enough to detect them. Thus, in addition to direct vapor measurement, two sampling strategies have been adopted by instrument designers. When contraband detection is based on air sampling without direct contact with the suspect object or person, then a means of drawing a large volume of air and trapping particulate matter and vapors is of vital importance. Modified hand-held or commercial vacuum cleaners, equipped with a removable filter for collecting particles, have been popular with some manufacturers and are widely applied in the field. Novel air-sampling systems with cyclones to separate particles according to their size have also been proposed. Another approach relies on swabbing (or swiping) and therefore requires actual physical contact between the suspect material and the sampling device, and is recommended when there are no time constraints for taking a sample and access to the suspect object or person is possible. The US Coast Guard has devoted time and effort to select the most suitable sample holder materials, and other law-enforcement agencies, such as the Drug Enforcement Administration (DEA) and the Federal Bureau of Investigation (FBI), have developed sampling procedures to ensure successful collection of particles and to minimize cross-contamination and interferences.

Both sampling strategies – vapor sniffing and particle collection – have been successfully applied, as demonstrated by the cases described in the following sections. Many IMSs also include an oven attachment, or heated inlet port, for vaporizing solid samples or for injection of liquid or gaseous samples, much like the injection port in GC.

Some IMSs have a membrane inlet that separates the ion source from the sampled ambient air, generally equipped with a hydrophobic membrane that rejects most of the moisture and allows the analyte molecules to permeate through it. This is advantageous when high levels of moisture are present, and also protects the IMS

Figure 2 Diagram of the Ionscan™ (Barringer) IMS. From left to right: the desorber heater unit for introduction of vapors emanating from swipe samples through the inlet unit into the ionization region with the $^{63}$Ni source, and then through the gating grid and along the drift region with its focusing rings and electric field gradient to the collector plate. (Reproduced with permission of Barringer.)
from dust, lint, and other contaminants. The membrane inlet is especially utilized in IMSs that operate at near-ambient temperatures as it reduces the clustering of water vapors with the reactant and analyte ions. The disadvantages of the membrane inlet are a reduction in sensitivity, longer response times and sometimes more severe memory effects.

A special type of inlet system, combining GC in the front-end of the IMS, is discussed in section 5.2, and is meant to overcome one of the major limitations of the IMS that arise from competitive ionization in mixtures, where compounds with a high PA or EN will interfere with the formation of ions in compounds with a lower PA or EN.

2.2 Ionization: Sources and Chemistry

In the original IMSs the ion source contained a radionuclide, usually a β particle emitter such as 63Ni or 3H (tritium) or an α particle source like 241Am. However, the regulatory obligations involved with using radioactive materials, and the costs inferred by adhering to them, created a driving force toward alternative nonradioactive sources. These include electrospray, photoionization (either from a laser or an ultraviolet (UV) lamp), corona discharge, surface ionization, and high-energy electron sources. Each has its own merits and limitations, as discussed in more detail elsewhere. To date, 63Ni is still the most commonly deployed ionization source, due to its long life, low maintenance and the fact that it has no power requirements. A gating system made of two wire grids (or two interwoven wires) is required to introduce a discrete packet of ions into the drift section (analogous to syringe used for injection of a sample in GC or high-performance liquid chromatography (HPLC)) and allows for the separation of ions of different mobilities.

The chemical processes that first lead to the formation of reactant ions and subsequently to production of analyte ions are rather complex. They depend to some extent on the type of ionization source used, but mainly on the gases and vapors present in the source region. For example, in the IMS source, trinitrotoluene (TNT) vapor in a pure nitrogen atmosphere will simply capture an electron to form TNT − ions (mass 227 Da), whereas in air, where the reactant ion is O2 −, a proton will be abstracted to form (TNT−H) − ions (mass 226 Da). The ion chemistry in the source may be, and often is, modified by doping the source with a substance (reagent) that changes the reactant ion. For example, addition of organochlorine compounds (such as CH2Cl2) would produce chloride ions, which could readily attach to analyte vapors (ethylene glycol dinitrate (EGDN) for example), and form EGDN−Cl − ions. Doping of the ion source is advisable when the analyte of interest may be present in a complex matrix, but has a high PA or EN.

2.3 The Drift Tube

This is the central part of the IMS and the quality of the instrument’s performance is determined mainly by this component. The chief function of this device is to separate ions of different types according to their mobilities and transport them from the gated ionization source to the detector, with as little loss and with as little peak broadening as possible. The conventional design relies on a direct current (DC) voltage gradient that creates an electric field along the drift tube and a purified gas stream (drift gas), usually at atmospheric pressure, that flows counter to the ion motion. The original design included a segmented drift tube design, where alternate conductor and insulator rings were joined together to form a pneumatically sealed tube and a voltage divider provides each conductor ring with a suitable voltage so that an electric field gradient is obtained. Simpler (and much cheaper) designs involve a series of thin conductor rings placed inside or outside a sealed tube or even, as proposed in the past, an insulator material (glass or ceramic) coated with a resistant material to form the field gradient. Some of these designs are so simple that they can almost be made at home. A novel design, called field ion spectrometry (FIS) by its developers and discussed in section 5.1, operates with an alternating current (AC) voltage to create a nonuniform electric field.

The drift tube in IMSs may be heated, which is usually the case for forensic applications, retained at room temperature (as with several hand-held models), or even cooled to subambient temperatures (mainly for research). Operating the drift tube at an elevated temperature is advantageous as it reduces clustering which may alter the drift times of reactant and analyte ions, thus causing difficulties in spectra processing; heating also shortens the clearance times after a sample was taken (which reduces memory effects). The electronic shutter (gate) is located at one end of the drift tube and the detector, usually a plate that serves as a Faraday cup, is at the other end (see Figure 1). The drift time of an ion is defined as the time it takes, under given operating conditions, to traverse the length of the drift tube and is, of course, instrument dependent. Therefore, it is customary to convert the measured drift time into more universal units, such as the mobility or reduced mobility, as explained above.

2.4 Signal Acquisition and Processing

A plot of the ion current at the detector as a function of the drift time (beginning when the gate opens) is called a mobility spectrum or, in the older terminology, a...
plasmagram. A typical example, showing that the vapors emitted from a wipe sample contained heroin (the peak at 10.35 ms) as well as the reactant ion (at 8.4 ms) is shown in Figure 3.

As seen from the x-axis, a single spectrum is acquired typically in less than 25 ms. However, the spectrum obtained from a single scan can be quite noisy due to electronic interferences and noise caused by the shutter grid. Simply by averaging several spectra, a matter of a few seconds, the signal-to-noise ratio may be improved considerably. As the shutter gate is typically open for 0.2 ms and spectrum acquisition takes 20 ms or more, only a small fraction (about 1%) of the ions produced in the source leave the shutter grid and are actually measured. A different approach, based on Fourier transformation, has been proposed (44) its main advantage being that a larger fraction of the ions can be utilized. However, this promising approach requires a second shutter gate near the collector plate together with more complex electronics and signal processing, and therefore has not been adopted by IMS manufacturers. In the novel FIS instrument, this problem is also overcome, as described in section 5.1.

Modern IMSs deploy microprocessors or computers for advanced signal processing. Their output may be in the form of a list of detected compounds (as on the right-hand side of Figure 3) with, or without, weighted probabilities. They may also be accompanied by sounding of an alarm or flashing a light when a hit is scored. Other software packages may store all the spectra for off-line processing by a trained operator or for use as evidence in court. It is generally advisable to have at least one reference compound for calibration of the mobility scale, as well as means for quality assurance. Commercial IMSs usually define a hit after testing whether an ion peak is within a preset drift-time window (i.e. a time position with a defined error), whether the peak width and amplitude meet the design criteria, and whether other peaks also appear in the proper position (when more than one peak is expected).

3 FORENSIC APPLICATIONS

For the purpose of the present article, the forensic applications of IMSs have been divided into three categories. The two main applications concern the detection of explosives and of drugs (illicit and prescription), whereas all other forensic applications are discussed in the third subsection.

3.1 Explosives

IMS technology has been successfully applied to detect hidden explosive charges, for identification of explosives in cases when a suspect substance had to be identified, or when postdetonation traces and debris were collected in order to obtain preliminary identification in the field of the type of explosive used or for selection of evidence for laboratory tests. The IMS is also considered for detection of taggants, which are substances with relatively high vapor pressures added to explosives by some manufacturers in order to increase their detectability (45,46).

Generally, when it is used for detection of explosives, the IMS is operated in the negative ion mode. In some scenarios the positive ion mode may be preferred, or a more definite identification may be achieved when both modes are used simultaneously or sequentially. Most common explosives contain nitro (i.e. NO2) functional groups which render the molecule somewhat electronegative, and therefore negatively charged ions are readily formed in collisions with electrons or less stable negative ions. The sensitivity of the IMS for the detection of explosives is because a large part of the charge generated by the ion source may end up as negative ions derived from the explosive molecules that were introduced into the ion source. Some types of explosives that do not contain such electronegative groups present the forensic chemist with a special challenge, as they may not be detected by the procedures used for common explosives. This is especially relevant for instruments that base their detection solely on nitro groups, but IMS operators may also be required to take special measures for these substances.

There are three major mechanisms of negative ion formation from most explosive compounds, and which serve as the basis for detection and identification of explosives by IMS (Equation 6):

\[
\text{charge transfer } \quad \text{M} + X^- \text{(or e^-)} \rightarrow \text{M}^- + \text{X} \quad (6a)
\]
where $M$ is a molecule of the explosive and $X^-$ a reactant anion. Charge transfer occurs when a negative reactant ion encounters an electronegative molecule, and an electron is transferred from this ion to the neutral molecule. Such a reaction channel will be dominant when the electron affinity of $M$ is higher than that of $X$ and other reaction mechanisms are less exothermic. Proton transfer, or proton abstraction, will take place when the analyte molecule has a labile proton and the proton transfer, or proton abstraction, will take place when the electron affinity of $M$ is higher than that of $X$. The third mechanism, association or clustering, may occur when the explosive molecule has an electrophilic site for binding the negative ion. Most explosives, particularly aromatic compounds that contain electronegative substituents, are good candidates for such reaction, although other compounds may also readily associate with small ions. One of the most common explosives, TNT, undergoes electron attachment (which can be viewed as a type of charge transfer) when there is no oxygen (only an inert gas or nitrogen) in the ion source, proton abstraction if $O_2^-$ ions from air are present, or association in the presence of chloride or bromide ions. Under certain conditions, several types of these ions may be formed simultaneously.

The product ions in Equation (6a–d) are all quasi-molecular ions, as they retain the parent molecule’s structure almost intact. However, fragmentation processes that lead to creation of sub-molecular ions may also occur, especially if the product quasi-molecular ion has an energy excess due to its exothermic formation process or due to the fact that the molecule or quasi-molecular ion is thermally unstable. Formation of $NO_2^-$ or $NO_3^-$ is quite common for explosives such as penta-erythritol tetranitrate (PETN). A comprehensive study of the complex fragmentation processes that occur in TNT, PETN, and hexahydro-1,3,5-trinitro-1,3,5-triazine (RDX) after zero-energy electron attachment emphasizes this point. Although the experimental conditions in that study were not similar to those prevalent in the IMS, it should be noted that between five and 13 different ions were observed in these compounds. In the IMS, the fragment ions from the thermally unstable compounds tend to form cluster ions, including at times clustered dimer ions as shown in Equation (6d), such as $RDX_2Cl^-$, with concentration-dependent relative intensities.

The improvement in sensitivity that can be obtained by doping the reactant ion has been quantitatively demonstrated. The signal intensity from EGDN increased by factors of 7 and 4.7 with bromide and chloride reactant ions, respectively, and the taggart DMDNB (2,3-dimethyl-2,3-dinitrotoluene), which gave no signal in the undoped IMS, gave a detectable signal with both these dopant ions.

Naturally, the more types of ions that are formed from a given analyte, the more positive is the identification of the explosive. However, if the charge is distributed between several ions, the intensity of each may be too small to be detectable.

Some examples that illustrate applications of IMSs for explosives detection and identification are given below. First is the use of IMSs for the identification of explosives residues in post-detonation debris. A Barringer Ionscan instrument was used to confirm and enhance results obtained by HPLC for samples collected at real detonation scenes. Debris with explosive residues were treated with acetone to perform solvent extraction: small samples in a Soxhlet system, medium-sized samples by sonification, and large samples by swabbing. The extracts were then filtered, reduced to a small volume, and dried under a stream of nitrogen. The dried samples were dissolved in acetonitrile and solid-phase extraction on a Florisil column was performed, followed by HPLC analysis. The HPLC fractions were collected, dried and redissolved, and placed on a Teflon filter and the filter was dried under a stream of dry air. Analysis by IMS was carried out according to the standard procedure of the Ionscan instrument and detection limits of a few hundred picograms were obtained. The authors concluded that the IMS results for several types of explosives compared well with those obtained by HPLC with a UV detector and that in some cases the IMS confirmed the presence of explosives at levels that were below the detection limit of HPLC.

Application of IMS technology to the detection of concealed explosives on personnel was recently demonstrated. The subject stands in a mock walkthrough portal, while an overhead fan blows air over the subject’s body (at approximately 2 m s$^{-1}$) so that explosives vapors and dislodged particles are carried through two vents (160 L s$^{-1}$) located close to the feet and collected by a preconcentrator (a filter screen that traps heavy organic molecules). After the sampling cycle is finished, the screen is heated in a stream of air (4 L s$^{-1}$) so that explosive vapors are desorbed into an IMS detector (phenylethylidine (PCP)-110). The whole process takes about 12 s, but installation of two preconcentrators and two IMSs should shorten the time per person. The system is claimed to be sensitive enough to detect subfingerprint quantities of RDX deposited on cloth patches as well as
TNT vapors (and possibly more volatile explosives and taggants).\(^{50}\)

Not all explosives contain nitro groups, a fact that may preclude their detection by techniques based on fluorescence from excited NO species. However, an undoped IMS (Graseby, chemical agent monitor (CAM)) can be used for some peroxide-based explosives, such as TATP (triacetone triperoxide) and its degradation products (namely DADP (diacetone diperoxide)), which have been involved in recent terrorist attacks.\(^{51}\)

An interesting test of the capability of an IMS to detect explosives was carried out at Toronto International Airport.\(^{52}\) Over 10,000 items, six of which were spiked with the explosive PETN, were sampled at a rate of 80–120 items per hour. Sampling was by direct vacuuming, swiping and swabbing. The false alarm rate was low (0.05\%) and success in detection of all six spiked items sampled by swabbing was reported.\(^{52}\) Figure 4 depicts a typical mobility spectrum and table of identified compounds obtained from the sample.

Table 1 presents a summary of the measured reduced mobilities and limits of detection (LOD) (where available) when using an IMS of some of the common explosives. In several cases, the operational conditions of the measurement are concisely given, such as the drift tube temperature, type of carrier gas and method

![Figure 4](image)

**Figure 4** A mobility spectrum and listing of the identified compounds (explosives), generated by an Ionscan™ (Barringer). Note that several of the compounds have more than one ion species (peak). (Reproduced with permission of Barringer.)

of sample introduction. The reduced mobility values shown in Table 1 are those that are judged by the author as being the best available values. These may differ somewhat between IMSs, according to the operational parameters, so that a calibration with a suitable reference material under the very same conditions is recommended. The tabulated LOD are based on reported values.

IMS technology for the detection of explosives is already in wide use for screening passengers and their luggage in airports, visitors and their bags in popular tourist sites (such as the Tower of London), and at restricted installations or security zones. However, screening large amounts of luggage and people is still time-consuming, and the slow procedures still cause queues to be formed during crowded periods. In addition, although the sensitivity of the IMS may be marginally satisfactory with detection limits in the subnanogram range, false readings (positive and negative) that arise from artifacts (mainly matrix effects that interfere with the detection or identification) demonstrate that this technology is not foolproof. The IMS must therefore be regarded as one of the powerful tools in the war against terrorism, but by no means the only tool.

### 3.2 Illicit Drugs and Drug Abuse

In this article, the term “illicit drugs” refers to substances that are outlawed and their possession is considered an offense (the quantity will determine how severe the offense is and the exact amount varies from country to country and state to state). The most common of these are the narcotics marijuana, cocaine and heroin, and the hallucinogens (psychedelic drugs) lysergic acid diethylamide (LSD) and psilocybin. As an offender will usually try to conceal the drugs the problem facing the forensic chemist is twofold: detection of hidden drugs, and obtaining identification once a suspect material is found. Drug abuse refers to prescription drugs, mainly barbiturates and amphetamines, that are used by people for nonmedical purposes (mood alteration).

Most of these drugs contain amine or amide groups, resulting in a relatively high PA, and therefore tend to efficiently produce positive ions, usually a protonated quasimolecular ion (Equation 7).

\[
\text{proton transfer } \quad M + BH^+ \longrightarrow MH^+ + B \quad (7)
\]

where M is the drug molecule and BH\(^+\) a reactant ion with a labile proton. This proton transfer reaction will occur with high efficiency when the PA of M is higher.
than that of B. Exothermic protonation may also lead to fragmentation of some of these quasimolecular ions and formation of smaller ions. Another process, frequently observed when the concentration of the analyte molecules is high, is the formation of protonated dimer ions, which can also be viewed as association of an analyte molecule with a protonated quasimolecular ion:

\[
\text{association (dimerization) } MH^+ + M \rightarrow M_2H^+ \quad (8)
\]

Equation (11) occurs because a symmetric proton-bridged species is formed. In principle, association between two different molecules may also occur, such as \(\text{MHB}^+\), but these ions are generally unstable because the proton would favor the species with the higher PA.

Some cases in which the IMS has been used to detect and identify drugs are discussed below. A scenario in which drugs are smuggled in a vehicle was simulated in order to obtain an estimate of typical levels that can be detected.\(^{53}\) It was found that all hard drugs left detectable traces on surfaces in the vehicle and its driver, as well as on secondary surfaces touched by the driver (Figure 3). A Graseby Narcotec\(^{TM}\) IMS (Figure 5), was used for detection of vapors that were generated by thermal desorption with a stream of hot air from wipe samples.

Typically, hard drugs (such as heroin, cocaine, ecstasy and amphetamines) were present in microgram quantities on primary contact surfaces, and therefore easily detected (above 10 ng per wipe). Cannabis detection depended on the nature of the material, due particularly to the weak transfer of THC (tetrahydrocannabinol, the active ingredient in hashish) to the wipe material.\(^{53}\)

Another interesting scenario, using a Barringer Ionscan\(^{TM}\), where it was necessary to detect drugs on board a ship has been described.\(^{27-30}\) The effect of different aqueous media (tap water, deionized water, seawater, and sweat) on the detectability of cocaine was tested, with particular attention given to the temporal behavior of the desorption of drug vapors. It was found that the presence of water delays the release of cocaine vapors which may lead to a false negative response. This can be overcome by extending the desorption time to 15 s or by performing a second desorption cycle. The presence of large amounts of methanol had little effect on the maximum amplitude of the cocaine signal. In a later work, Su et al. tested the effect of the presence of oil on drug detection whose desorption was delayed. Once again, the oily sample was heated in a programmed temperature ramp, so that the initial release of the oil vapors did not interfere with the detection of the drug.\(^{54}\)

A particularly innovative idea was to apply an IMS to the detection of drug residues in hair samples.\(^{55-57}\) Alkaline digestion (5 M NaOH in a 4 : 1 methanol–water medium) was used to unbind methamphetamine, MDMA (the abusive drug “Adam” or “Ecstasy”) and MDEA (the abusive drug “Eve”) prior to vaporization and IMS analysis (both MDMA and MDEA are derivatives of MDA (3,4-methylenedioxyamphetamine)). The use of an internal standard made it possible to obtain quantitative results using an IMS, with good agreement with the laborious conventional gas chromatography/mass spectrometry (GCMS) method.\(^{55,56}\) Analysis of 20 mm long sections of hair taken near the scalp and further from it can yield information on the drug abuse habits of the subject.\(^{57}\) Washing the hair sample to remove external traces prior to analysis was necessary to obtain results that truly reflect the abuse habits. The reported detection limit for methamphetamine (MA) was 0.5 ng per milligram of hair.

In this article, the term “drugs of abuse” refers to substances that may be legally used, but either require prescriptions or are used in excess of the recommended amount. The IMS may be used to identify such substances.
and help investigators and medical personnel determine what treatment is required. In these scenarios the emphasis would be on rapid positive identification of suspect substances rather than on detection of hidden contraband materials. For example, skin surface sampling and sniffing, in combination with IMS detection, were used to screen patients with suspected drug abuse and overdoses in an emergency room scenario. The response of the drug psilocybin, used for mind alteration, has been recently characterized by the IMS with good detection limits.

Table 2 presents a compilation of useful data required for identification of common illicit drugs and popular drugs of abuse, including the reduced mobility and LOD where available. Most of the reduced mobility values and LOD were taken from the reviews by Keller et al., other data were taken from the Barringer Ionscan™ tables and from the review by Karpas. The LOD for most drugs is on the order of 1 ng, which represents the minimum amount of substance on the sampler (swab or filter) required for obtaining a positive response under normal operating conditions. Depending on the laws of the country, the IMS could be used for screening only, and subsequent positive identification by other techniques (usually GCMS) may be required for judicial procedures.

3.3 Other Applications: Tear Gas, Arson, and Chemical Warfare Agents and Biological Materials

These forensic applications are grouped together either because the IMS is not yet as widely recognized as suitable for their detection or identification (arson and tear gas), or because they are not generally considered as classical forensic applications (chemical and biological warfare agents (BW)). In some cases, the realm of forensic science may not be clearly defined; for example, detecting spoiled fish may be considered as a pure health hygiene problem or may be regarded as prevention of a criminal act.

3.4.1 Tear Gas

“Tear gas” is the generic name given to a group of lachrymatory chemical compounds. They are used as a nonlethal riot-control agent by law-enforcement authorities worldwide as well as for personal protection by individuals (although fatalities from severe exposure are known). Tear gas is increasingly being used in criminal acts as an offensive weapon. The IMS has been used to characterize the common tear gas sprays and a commercial Riot Agent Monitor™ is available which detects CN, CS, and BBC (bromobenzyl cyanide). A detailed study of CN, CS, and their isomers, and also the residues and degradation products found after their use, has been reported. Positive mode and negative mode spectra were obtained. The detection limits for CN were 0.1 µg and 0.5 µg for the two modes, respectively, whereas CS was only identified in the negative mode at levels of 10 mg and 16 mg at ambient temperature and 50°C, respectively. At higher temperatures (even 75°C) analyte ion peaks were not observed in either mode. Thus, it was pointed out that the IMS can be used for screening of suspect spray cans and to identify the use of tear gas from residues on clothes or on swipe samples.

3.4.2 Arson Cases

The IMS has been used to detect the presence of accelerants at the scene of arson crimes, and to help investigators locate the site where the fire was started and gather evidence for further, more definitive, laboratory testing. This is just one example of where the portability of the IMS can be of help on the scene for screening debris and collecting meaningful samples which, after more analysis, may be presented in court.

3.4.3 Detection of Chemical Warfare Agents and Biological Materials

Although CWA detection is not usually considered as part of the forensic sciences, CWA use in terrorist attacks is already on record. Another reason for the inclusion of CWA detection in this section is that the most widespread application of IMS technology is in this field – these instruments are the mainstay in several countries for military and civilian defense purposes. Hand-held IMSs such as that shown in Figure 6 are used to alert troops to dangerous levels of CWA and to monitor personnel, equipment and areas suspected of being contaminated after an attack. Pocket-size IMSs may be used by personnel in the battlefield for similar purposes (Figure 7).

Portable instruments are used by emergency response teams and other stationary IMS systems have been developed to monitor the air intake in armored vehicles, as well as in ships or in military and civilian installations and in populated areas. This success of IMS technology results from its sensitivity toward these highly toxic chemicals (Table 3) and that specific IMS instruments are relatively inexpensive and easy to operate and maintain.

Unlike the detection of concealed drugs and explosives, where the objective is to try and detect a substance that is hidden while the perpetrators try to prevent vapors from being emanated, when monitoring for CWA it is necessary to detect only those substances that are present (substances are harmless if not present above a certain level). In other words, searching for explosives

**Notes**

- Based on Keller et al.<sup>13,14</sup>
- Reduced mobility values based on Karpas review.<sup>12</sup> Barringer database, or Keller et al.<sup>13,14</sup> Some ion identifications were confirmed by Lawrence using IMS/MS. Most values are consistent within 0.01–0.02 cm$^2$V$^{-1}$s$^{-1}$, unless other ion species were observed.
- Air or N$_2$ = air or nitrogen were used to carry the sample, for the ionization source and drift gas flow; 150, 166, 200 or 250 is the drift tube temperature in degrees centigrade; wire = insertion of a metal wire with absorbed vapors or solution; cart = sample was introduced from skin onto a cartridge and then thermally desorbed; skin = sampling subject by swabbing skin surface; sol = introducing sample by evaporating a dried solution droplet. EC, ecgonine methylester.
is looking for something that supposedly “isn’t there”, whereas when looking for CWA the concern is about what “is there”.

Detection of biological substances in general, and BW in particular, is a relatively new field for IMS technology. Once again, use of BW or other toxins in forensic investigations is not very common, although their potential use in certain crime scenarios cannot be ignored. The response of the IMS to the presence of biological materials is sometimes an indirect one in that the action of the active biological materials releases a chemical substance, and that substance is detected by the IMS. More direct methods have been developed which detect biomarkers using a pyrolysis–GC/IMS (gas chromatograph ion mobility spectrometer) configuration.

4 ION MOBILITY SPECTROMETERS IN THE FIELD AND IN THE LABORATORY

4.1 Operational Considerations

The type of IMS chosen would depend on the application and on operational considerations, with different types used in different scenarios. IMSs may be used as laboratory instruments for detection and identification of substances that were sampled elsewhere, either without pretreatment or after some chemical procedures have been carried out to preconcentrate the analyte and remove interferences. If a rapid response is required, as in the examination of luggage or the screening passengers entering an airport terminal, an IMS may be installed on-site. A number of fixed-point IMSs may be connected in a network in a railway station, for example, to monitor the presence of a chemical agent to counter terrorist attacks. If custom authorities or coast guard units need to examine cargo in a container, the IMS must be brought on-site and therefore hand-held devices are advantageous. Finally, if personnel need to be alerted to the presence of hazardous vapors or gases, pocket-size instruments may be used that

continually sample the ambient air and sound an alarm if a threshold is exceeded.

4.2 Sampling for Detection of Hidden Contraband Materials

A simplified statement of the main problem involved with detection of hidden contraband materials is that of “bringing enough analyte molecules to the IMS”. Once the concentration of analyte vapors is high enough, positive identification may be achieved and detection obtained. The amount required for most common explosives or drugs is on the order of \(10^{-8} \ldots 10^{-11}\) g, depending on the analyte, the matrix in which it is present, and the instrument.

The sampling system must be capable of collecting vapors that emanate from contraband materials that, on the one hand, have relatively high vapor pressures (like dynamite) and, on the other hand, should trap and concentrate microparticles from those materials that have low vapor pressures (as do most drugs and plastic explosives). These two demands are somewhat contradictory as sampling large volumes of air would bring more of these particles to the IMS but may also dilute the analyte vapors present near the suspect material with room air from other areas, thus reducing the vapor concentration to undetectable levels. In practical terms, an efficient sampling system must perform the following steps: detach analyte microparticles from the surface of the contraband packaging material or person, carry the particles and vapors to the preconcentrating device (a filter, for example) that allows the air to pass through it while trapping the analyte molecules, and then the trapped analyte particles must be easily vaporized and introduced into the IMS ionization region. Sampling may be performed with a modified vacuum cleaner equipped with a filter for trapping the microparticles and special portals for screening personnel or luggage have been developed for this purpose.

Several search methods, based on swabbing or swiping, rely on physical contact between the suspect material and the sampling device. A suitable sampling medium (cotton, cotton-wool, paper, etc.), that can be either dry or wetted with a solvent, is rubbed on the suspect package or hand and then placed in a heated sample introduction port (Figure 8). The particles taken up by the swabbing action are vaporized in a stream of carrier gas (usually air) that transports them into the IMS, where they are ionized and detected.

4.3 Sample Preparation

Detection of gases or vapors by the IMS can be done by direct sampling of ambient air, if the concentration is in the ppb to part per million (ppm) range, and in some cases even ppt concentration may yield a clear signal. In such cases, no sample preparation is required. However, when particulate matter is trapped on a filter, or swab and swipe samples are collected, the sampling medium has to be heated so that vapors enter the IMS. Thus, in several IMS models, particularly those used for forensic application, a small oven is coupled to the IMS inlet, and the sampling medium is inserted into this oven and sealed, so that a stream of purified air (or another gas) carries the vapors emanating from the sample into the ion source (Figure 5).

If, for example, detection of drugs in hair samples or explosive residues is the application, then more elaborate procedures need to be carried out, as described in the previous sections. In such cases, the sample is usually treated with a suitable solvent, which may then be evaporated to a minimal volume and injected into the heated inlet in a fashion similar to GC samples. Very complex procedures are generally not performed for routine analysis by the IMS.

4.4 Sensitivity and Limit of Detection

The LOD of an IMS, like any other gas sensor, may be expressed in terms of the minimum detectable concentration of the analyte vapors in air, and is in the ppt to ppm range for most explosive and drug vapors. A more practical definition is that microparticles from nonvolatile substances are trapped and collected on a sampling medium, which is then introduced into the heated oven. In this case the LOD is expressed in terms of the minimum detectable mass of analyte on the sample, which is in the picogram to nanogram range for most explosives and drugs. Tables 1–3 summarize selected...
LOD, as reported by independent researchers and by some of the major manufacturers of IMSs in the forensic market. These summaries are based on published works and on the claims made in the most recent brochures and promotional literature available at the time of writing. Table 4 summarizes some of the values that represent the vapor pressure or equilibrium concentrations of common explosives and drugs.

5 RELATED AND HYPHENATED ION MOBILITY SPECTROMETRY TECHNIQUES

5.1 Field Ion Spectrometry

FIS is a technology in which mobilities of ions in an AC electric field are determined by scanning a voltage, instead of by measurement of drift times in a static DC electric field as in classical ion mobility spectrometry. Nevertheless, the two techniques are closely related as both depend on API processes for ion formation and on the fact that ions may be separated according to their different mobilities. FIS was initiated in the former USSR and was first presented in a paper as recently as 1993. Commercial interest and support has given the technique a considerable boost. Although not yet in wide use, FIS is being evaluated by government and law enforcement agencies in several countries and, as forensic applications appear to be most promising, the technique warrants some discussion.

The principle of FIS is reminiscent of a quadrupole MS, i.e. the device operates by filtering ions as they travel from the ion source to the detector through parallel electrodes across which an oscillating electric field is applied. Figure 9 is a diagram of an improved FIS design, with separate sample and carrier streams to overcome the detrimental effect of uncontrolled moisture levels in the sample on the ion mobility. Ions are injected into the carrier stream in the space between the inner and outer electrodes, and travel along the ion filter until they reach the ion collector. The path along which an ion travels depends on its mass, size, shape and charge. By sweeping a second voltage, known as the compensating (or traverse field) voltage, different ions are allowed to reach the detector. The plot of ion current as function of the compensating voltage, called an ionogram, is equivalent to the mobility spectrum in conventional IMSs, as shown in Figure 10 for some explosives.

The enhanced sensitivity of FIS instruments arises mainly because its duty cycle is close to 100%, whereas the need for a shutter-gate in a conventional IMS allows only about 1% of the ions formed in the source to be detected.

The reported LOD for several chemical substances of relevance to forensic science (Table 5) are superior to those attainable by a conventional IMS. Furthermore, the controllability of the high-field conditions of FIS can be advantageous in reducing some of the interferences that hinder the conventional IMS, such as overlapping peaks

resulting from ions with similar mobilities. However, skilful operation of FIS under optimal operating conditions, requires more training than the simple IMS, and it is more difficult to predict the mobilities of new chemicals, or to estimate the molecular weights of peaks that appear in the mobility spectrum of FIS. The technology relies on the high-field effect on the mobility of the ions, $K$, which may be expressed by: $K = K(0) \times \alpha \times E^2 + \cdots$, where $\alpha$ is another unknown and can be related to $+ve$, $-ve$, or a more complicated expression. Calibration of the high-field effect is required for each ion.

5.2 Gas Chromatography Ion Mobility Spectrometer

As mentioned above, one of the main limitations of the IMS arises from competitive ionization processes in
mixtures, which may hinder the formation of ions from some analytes, whereas the measured concentration of others may be distorted. In order to overcome this, a GC column may be used to separate the sample into discrete components before they enter the ionization source. As both the IMS and GC operate at ambient pressure, their coupling need not involve elaborate pumping systems. However, attention to some technical details is required so as to reduce memory effects. This mainly concerns proper positioning of the column-end in the IMS and use of a make-up gas stream to transport the analytes as they elute from the capillary GC column to the ionization source.

It is interesting to note that this idea first appeared when the IMS was introduced\(^{(73)}\) as a laboratory GC/IMS/MS instrument. In addition to simplifying the mobility spectra, the GC/IMS affords two-dimensional information for positive identification of components in mixtures: first a retention time is derived from the GC data (in some instruments the IMS serves as a detector for GC by monitoring the decrease in the reactant ion peak, as an indication that a chemical has entered the ion source), and then mobility spectra may be examined and the peaks compared with a library of mobility spectra (just like GC/MS). The main drawback of this technology arises from the relatively long time required for separation on a GC column, therefore making it less suitable for field applications. Evolution of IMS and GC technologies, and developments in microelectronics have led to the introduction of hand-held fast GC/IMS instruments,\(^{(74)}\) first for the military and later for civilian purposes. An example of the latter is the EVM\(^{75}\) (Environmental Vapor Monitor). A recent innovation combines a novel pneumatic sampling system that prevents saturation with the separation capability and speed of a high speed capillary GC column and the sensitivity of the IMS. This is known as the EVM-II or by the acronym AVS/TLGC/IMS (automatic vapor sampling/transfer line gas chromatography/ion mobility spectrometer).\(^{(75)}\)

5.3 Ion Mobility Spectrometer Mass Spectrometry

The combination of IMS and MS involves differential pumping to overcome the pressure gradient between the ambient pressure IMS and the \(10^{-5}\) torr operating pressure of MS, as well as a system of ion lenses to transport the ion cloud from the IMS detector region into the MS device. The only manufacturer of custom made IMS/MS systems is still the original inventor of modern IMS technology (PCP, Inc.), although some API/MS systems may be quite easily converted into IMS/MS. The IMS/MS is a typical laboratory system, with large power requirements and heavy equipment although, judging by recent trends in MS, portable IMS/MS is a realistic expectation. The main advantage of the IMS/MS system is that it affords positive identification of the ions formed in the IMS, and is vital for establishing a correlation between mobilities (ion drift times) and masses (required in some court cases). If forensic applications of the IMS are viewed mainly as a screening technique, then the IMS/MS data is the linchpin on which a court case may rest.

6 MERITS, LIMITATIONS, AND FUTURE TRENDS

6.1 Merits and Limitations in Forensic Science

The main advantages of the IMS for forensic applications arise from its sensitivity, portability, simple operation even by nonexperts, and its price, all of which make IMS a powerful tool for screening. Its major merit is derived from the sensitivity of the method which requires as little as a nanogram of contraband substances for detection and identification purposes in a short time, with relatively few false-alarms. The fact that IMSs can easily be carried to the scene or can directly examine suspect personnel or objects, and that elaborate laboratory pretreatment is not usually required is another advantage for field applications. Little training is required for operators and the results may be presented in an unambiguous manner, which enables law-enforcement officers to obtain relevant evidence for further laboratory processing which may be used in court. Finally, the price of hand-held instruments, and even of the more sophisticated portable systems, and the minimal maintenance requirements are low enough for widespread use.

All these advantages are valid only when suitable applications are selected. Fortunately, detection of most explosives is relatively straightforward, due to the efficient production of negative ions from the analytes, and detection of the common drugs relies on the high PA and the tendency to form stable positive ions. However, the detection of some explosives and drugs requires special operational procedures, as they do not respond in the conventional mode of operation.

IMSs have some limitations which affect their applicability in some scenarios. For example, if quantitative information is necessary, the IMS with its limited dynamic range and problematic response to mixtures may not be able to provide the required data. Further limitations may be imposed by unfavorable operational conditions, such as high humidity or the presence of interfering substances at the sampling point. Naturally, some substances are not suitable for IMS detection owing to their chemical properties.
6.2 Future Developments

The future trends of IMS technology in general, and its application in forensic sciences, are already reflected in presentations and publications. Some of these improvements may require a sacrifice, or a trade-off, of some of the features that make the technology so appealing, namely price, size, simplicity of operation, and portability.

6.2.1 Nonradioactive Sources

The emergence of alternative ionization sources that do not require radioactive materials is evident from the number of papers presented in the most recent IMS workshops. Some of these sources may even be superior to the traditional $^{63}$Ni in view of their higher ion production capability (an extended dynamic range and diminished saturation problems) as well as their flexibility in operational conditions which may lead to better selectivity and specificity. Furthermore, ionization of less-volatile compounds, particularly those of higher molecular weight, may be possible with devices that spray a solution with a dissolved sample, rather than vapors, into the IMS, like electrospray and ion spray sources. Other developments may include flame or pulsed-flame ionization sources that will be element specific, rather than compound specific.

6.2.2 Increasing Sensitivity

IMS technology is rapidly approaching picogram sensitivities (of the order of a billion molecules), which is typical of the most advanced explosive detectors of the present generation. Further improvements in sensitivity could arise from more efficient ionization and ion introduction processes (most gated IMSs use only 1% of the ions), more efficient drift tubes for better ion transmission, collection and detection, improved ion chemistry, and better signal acquisition and processing. For example, sophisticated strategies of ion collection (bunching), in analogy to the ion trap mass spectrometer, could yield great benefits. The idea is to thermally desorb the vapors from the sample, or to introduce vapors, for a few seconds, while collecting the ions of interest (rejecting other ions to avoid large space charges), before sending them in a short pulse, as a preconcentrated ion pack, down the drift tube. This works well under high-vacuum conditions; it may encounter difficulties, and possibly insurmountable practical problems, at atmospheric pressure. Improved detectors, similar to electron multipliers, that operate at near-ambient pressures could replace the traditional collector electrode. A noteworthy development is the use of novel drift tubes that deploy a dynamic AC electric field (rather than the traditional static DC field) and a reduced operating pressure (subambient), such as with the FIS instrument.

6.2.3 Improved Sampling Methods

The two key factors in detection of hidden contraband materials are collection of enough molecules (vapors or particles) and a sensitive detector. Direct sampling of vapors has a built-in paradox: high sampling rates are required to carry over enough vapor from across the room (or wherever the contraband material is) which will lead to dilution of the vapors to perhaps undetectable concentrations, whereas low sampling rates may not be sufficiently effective in bringing the vapor to the detector. Particle collection by swipe sampling may not always be possible, either because of time restrictions or because direct contact is not feasible. Therefore, better sample collection and preconcentration is the most promising avenue for enhanced detection capability. This could be done by using an approach similar to that deployed in the analysis of particulate matter in air, with an additional device for vapor collection, probably based on a liquid medium for dissolving the vapor and amassing the particles.

6.2.4 Smaller Detectors

One evident trend is toward smaller, even personal or lapel-worn, IMS-based detectors and monitors. These could be carried around unobtrusively by security personnel in airports, customs, sensitive installations, and public areas to continuously sample the environment for presence of explosives, drugs and potentially hazardous chemicals. These detectors would have to be cheap and simple, which could be achieved with mass production techniques.

6.2.5 Explosives Not Containing Nitro Groups

Preliminary work indicates that the IMS can be used to identify explosives such as TATP, which some other techniques are incapable of doing. Further development is required, both to overcome the ever-changing chemistry resulting from the instability of such compounds, and to enhance the detection capability.

ACKNOWLEDGMENT

The assistance and information given by colleagues in the IMS field and by commercial companies that allowed their photographs to be used are gratefully acknowledged. Special thanks are due to Dr Alan Brittain for critically reviewing the manuscript and for his suggestions and comments.

Recent advances in DNA technology for the detection of variation in specific DNA sequences have proved that DNA fingerprinting analysis can become a very valuable technology for forensic applications. By analyzing a sufficient number of regions of DNA that show variability between nonrelated individuals, one can reduce the probability of two individuals matching by chance, to practically zero. Thus, it can be demonstrated that an individual's genetic fingerprint is as unique as their skin fingerprints, and often easier to obtain. However, the requirements for DNA fingerprinting for forensic application involve not only the technology but also the cost, time and reliability of the analysis. DNA fingerprinting technology has tremendous power of exclusion and inclusion and is used routinely as legal evidence. Due to the high reliability of DNA fingerprinting, courts often require DNA analysis as evidence in the most serious criminal cases. However, present gel electrophoresis analysis of DNA in forensic applications is considered to be slow and expensive. Consequently, a backlog of DNA analysis for forensics is common. Mass spectrometry DNA analysis can help to resolve this difficulty, since it can be faster, cheaper and more reliable for forensic sample analysis.

DNA fingerprinting is a technology that identifies individuals based on patterns of DNA markers detected in the genomic DNA. It can be used in forensic analysis to identify suspects or victims. It is particularly valuable at scenes of violent crimes where a body may not be available, or in instances where decomposition or dismemberment excludes the use of standard forensic techniques. There are several different approaches available to obtain DNA fingerprints for forensic application. These include restriction fragment length polymorphism (RFLP), short tandem repeats (STRs), single-nucleotide polymorphism (SNP) and DNA sequencing. Currently, the bulk of RFLP, STR, SNP analysis and DNA sequencing utilize gel electrophoresis, which is time-consuming and labor intensive. With the newly developed mass spectrometry technology for DNA analysis, the analysis time can possibly be reduced by more than 90% and automation of sample analysis is much easier. Furthermore, mass spectrometric analysis does not require the use of chemical dyes or radioactive materials, thus increasing safety and reducing cost in sample preparation and handling. In addition, the cost and concern of disposing of hazardous waste are eliminated.

The major difficulties preventing the use of mass spectrometry for DNA analysis are the very low vapor pressure of DNA and the fragmentation of these large DNA molecules by most ionization methods. In 1987, Professors Hillenkamp, Karas and their colleagues successfully developed matrix-assisted laser desorption/ionization (MALDI) for protein analysis. In this approach, a protein sample was mixed with a much larger quantity of small organic compounds which serve as a matrix. These matrixes, such as sinapinic acid, functioned to prevent the protein molecules from becoming entangled with one another. In MALDI, the DNA sample is irradiated with a laser beam, which causes desorption. The wavelength of the laser is often chosen so as to have strong absorption by the small matrix molecules, but not the protein. After the absorption of the laser photons by the matrix molecules, the matrix molecules are vaporized and carry the much...
larger protein molecules into space. Some ions and electrons are also produced due to this laser ablation process. Some protein ions can be produced by protonation or deprotonation processes caused by the interaction of desorbed protein molecules and desorbed matrix molecules or ions.

During the past few years, MALDI has also been successfully applied to DNA detection through the discovery of new matrixes and improvements in instrumentation. The main advantage of MALDI analysis is its very fast speed. However, the size of DNA fragments which can be detected is still limited to less than 3000 base pairs (bp). Mass spectra for DNA fragments larger than 100 nucleotides usually have poor mass resolution ($M/\Delta M < 200$). Nevertheless, there are many forensic applications using mass spectrometry for DNA analysis which are not limited by modest mass resolution and detection efficiency of large DNA fragments.

1 INTRODUCTION

1.1 Characteristics of DNA

DNA molecules are present in all living cells. In general, DNA contains a repeated structure of four different molecules: adenine (A), guanine (G), cytosine (C) and thymine (T). The chemical structures and molecular weights of these four molecules are shown in (1). The geometric structure of DNA was found by Watson and Crick to be a double helix with antiparallel chains of deoxyribonucleotides. The strands are joined by complementary base pairing consisting of hydrogen bonding between A and T, and G and C. Owing to the strong A–T and G–C coupling, the length of a double-stranded DNA (dsDNA) molecule is often referred to as the number of bp. In a human cell, there are 23 pairs of chromosomes, which together contain the estimated 3.6 billion bp of the human genome. DNA identification analysis in general refers to the specific features of an individual genome. Every person has a unique genotype (genetic make-up) which subsequently leads to different phenotypes (physical manifestation of genotype). Although all humans have all the same genetic make-up, there is a great deal of difference in nucleotide sequence between different individuals. The DNA sequence of any individual is identical even when it is extracted from different cells. The individual’s genetic uniqueness and identical DNA sequence within all tissues of the same person provide a strong basis for using DNA typing for individual identification through DNA fingerprinting.

1.2 Brief Historical Review of DNA Typing for Forensic Applications

The foundation of DNA typing for person identification was established by the observation of RFLP in which polymorphic DNA loci are determined from restriction enzyme digestion. In 1985, Jeffreys et al. discovered 33 and 16 bp repeated structures vary in number between different individuals, referred to as minisatellites, that can be used for fingerprinting. In 1987, Nakamura et al. reported the isolation and characterization of variable numbers of tandem repeats (VNTRs) for single locus DNA profiling. More recently, emphasis has been shifted to the typing of STRs because of the high reliability resulting from the large number of STRs in the human genome. In the last few years, it was discovered that SNPs occur once every 300–1000 bp in DNA fragments. Thus, SNP typing is expected to become a very reliable tool for person identification in the future. The ultimate accuracy of DNA fingerprinting for personal identification will be achieved once the entire human genome is sequenced. At present, the time and cost factors prohibit the use of sequencing the entire genome for forensic purposes. However, the rapid progress in sequencing technology as a result of the Human Genome Project suggests the possibility of using a sequencing approach for forensic applications.

1.3 Forensic DNA Sample Preparation

In the process of using DNA typing for forensic application, it is critically important to have very reliable and stringent protocols established. The major steps for DNA typing often include:
1. Sample collection: blood, buccal cells and hair follicles are the general sources for fresh DNA. For dried stains, samples should be collected and maintained in a dry, cool state. For autopsy tissue, it can be more reliable to have samples from more than one organ. All samples must be labeled with the source, tissue type and the time and date of sample collection.

2. Storage and transport: DNA samples can be stored and shipped as nonextracted tissue, a lysate with tissue in an appropriate EDTA (ethylenediamine tetraacetic acid) solution or fully extracted pure DNA. For nonextracted tissues, sample refrigeration during shipping is often recommended.

3. DNA extraction: standard phenol–chloroform extraction and alcohol precipitation processes are often used to extract DNA from biological samples. An automated DNA extractor such as the nucleic acid extractor (Applied Biosystems, Perkin Elmer) can achieve high-quality extraction. It is desirable to complete DNA extraction as soon as possible.

4. DNA amplification: DNA amplification is often necessary to increase the quantity of sample available for analysis. The polymerase chain reaction (PCR) is the standard technique for the amplification of a selected DNA segment. Since an amplification of $10^6$ or more can be achieved by PCR, any contamination by other DNAs can lead to a false conclusion. Thus, great care must be taken to prevent cross-contamination of sample material at the collection site and at any time during the analysis.

5. DNA size or sequence determination. This is the ultimate step leading to the conclusion of person identification. Up to now, gel electrophoresis has been used for both DNA size determination and sequencing. In this article, analysis by mass spectrometry will be emphasized.

1.4 Population Genetics for Reliability Estimation

The primary goal of DNA profiling for forensic application is to get the assurance of a match (inclusion) or mismatch (exclusion) of the evidence DNA sample with the suspect or victim’s sample. In general, DNA profiling can be used easily to rule out the suspect when DNA typing between suspect and evidence shows clear differences. Thus, DNA fingerprinting is a powerful tool for proving that an individual does not match the DNA collected at a crime scene. On the other hand, if the DNA profile from the evidence sample matches with the suspect, there is still a possibility that the evidence DNA comes from another person. It might be a coincidental match between two persons having similar DNA profiles. Thus, population genetics plays an important role in suspect identification. The simplest approach is to assume mating is random. The random mating of persons produces the same genotypes as random combinations of sperm and egg. Assume at a locus X, that 10% of the alleles are $X_1$ and 12% are $X_2$. For an $X_1$ homozygote ($X_1X_1$), the frequency is $10\% \times 10\% = 1\%$. For a heterozygote ($X_1X_2$), the frequency is $10\% \times 12\% \times 2 = 2.4\%$. Random mating populations are described as being in Hardy–Weinberg (HW) equilibrium. Although local populations (especially small populations) are not usually strictly randomly mating, the HW calculation provides a good approximation when no special genetic linkage is involved. For subpopulation groups such as people in an isolated village, the random mating approach is not generally a reliable assumption. However, it can probably be used as a guide for the minimum number of loci to be analyzed for the confirmation of matching suspect and evidence.

Since the confirmation of matching the suspect with the evidence DNA often requires the analysis of several loci, the time needed for DNA profiling can be long and the cost high. At present, all forensic DNA samples for court evidence are analyzed by gel electrophoresis. Visualization of DNA in this procedure requires the use of either radioactive material or dye tagging. VNTR electrophoretic analysis, especially with radioactive probes, can take several weeks to finish the analysis of different loci for forensic confirmation. The human factor introduced by lengthy handling increases the risk of error or contamination and reduces reliability. It is obvious that a faster, less expensive and more reliable method is required for processing the large number of forensic samples.

1.5 Gel Electrophoresis for DNA Analysis

The principle of gel electrophoresis is to separate different size DNA fragments by their different migration speeds in gel when an electric field is applied. Electrophoresis through an agarose or polyacrylamide gel matrix is the standard method used to separate, identify, and purify DNA segments. Agarose and polyacrylamide gels can be poured in a variety of shapes, sizes and porosities with different configurations. The selection of these parameters primarily depend on the sizes of DNA fragments to be separated. Polyacrylamide gel can have single base resolution for DNA fragments smaller than 500 bp. Due to their high resolution, polyacrylamide gels are often used for DNA sequencing. However, handling acrylamide gels is often tricky and requires skill and experience for reliable and reproducible results. Polyacrylamide gels also take a long time to run, and staining requires additional lengthy steps. Agarose gels have a lower resolution power than polyacrylamide gels.
but have a greater range of separation and generally run faster and are easier to stain. DNAs up to 50 kbp can be separated. Larger DNA fragments up to 10 Mbp can be pursued by pulsed gel electrophoresis.\(^9\) The detection of DNA with gel electrophoresis needs dye tagging such as ethidium bromide, or radioactive material tagging such as \(^{32}\text{P}\) or \(^{35}\text{S}\). However, the migration speed depends not only on the molecular sizes of DNA but also the conformation of DNAs, gel concentration, electrophoresis buffer, presence of intercalating dyes, etc. For example, circular DNA and linear DNA with the same molecular weight can have different migration speeds. Ethidium bromide can reduce the electrophoretic mobility by more than 10%. With a mass spectrometric approach to DNA analysis, all parameters which can change the ion mobility, except the size of DNA fragments, are no longer a concern.

### 1.6 Matrix-assisted Laser Desorption/Ionization for Biomolecule Detection

It is naturally logical to consider a mass spectrometry approach for DNA sequencing, since the development of mass spectrometry for large bio-organic molecules detection has already aroused major interest for decades.\(^10\) In particular, the principle of a time-of-flight (TOF) mass spectrometer is somewhat similar to gel electrophoresis. However, most mass spectrometric approaches failed to keep the large biomolecules intact during the vaporization and ionization processes. In order to overcome this difficulty, mass spectrometry coupled with electrophoresis for DNA analysis was pursued.\(^11\) In 1987 Karas et al.\(^12\) discovered that large protein molecular ions can be produced by laser desorption without much fragmentation if these biomolecules are mixed with small organic compounds that serve as matrices for strong absorption of a laser beam. This process is now called MALDI. The typical preparation technique for MALDI is to dissolve biomolecular samples in solution, then prepare a matrix that contains small organic compounds such as 3-hydroxypicolinic acid. These sample and matrix solutions are subsequently mixed and a small amount of the mix is placed on a metal sample plate to dry. After the organic material crystallizes, the sample plate is placed in the mass spectrometer for analysis. During the MALDI process, matrix materials strongly absorb the laser energy and quickly become vaporized. Large biomolecules are carried along during the fast vaporization process. By this method large biomolecules can be delivered into space without breakup, which is probably due to the minimal direct absorption of laser energy; thus, “soft” desorption can be achieved. Furthermore, it has also been found that protein ions can be produced during the laser desorption process, in addition to the expected neutral molecules. Ionization is thought to involve a proton transfer process.

Most MALDI experiments have been carried out by using a TOF mass spectrometer for mass determination, since TOF mass spectrometers have the advantages of simplicity, high sensitivity, fast speed, probing the whole mass region, and nearly unlimited mass range. The schematic of a MALDI device is shown in Figure 1. A pulsed UV or IR beam is used to achieve matrix-assisted desorption and ionization. The target plate with biological samples is usually biased to 20–50 kV for ion acceleration. The field free drift region for a linear TOF mass spectrometer is for the separation of different sizes of biomolecules. A reflectron TOF mass spectrometer is often used to improve the mass resolution for protein samples. However, spectra of large DNA molecules by a reflector TOF often fail to achieve the same degree of improvement on mass resolution because of the limited lifetimes of DNA ions produced by laser desorption.\(^13\) The detection of DNA ions is typically by an electron multiplier or a channeltron or microchannel plates. When the front surface of the detector is impacted by biomolecular ions, secondary electrons can be ejected and then subsequently be amplified by the detector, a fast preamplifier and amplifier. The output is fed into an on-line computer for data processing. Several commercial instruments have the capability for automatic sample preparation and data processing for peak identification and resolution determination. In addition, it is plausible that portable MALDI/TOF mass spectrometers can be developed in field use by forensic investigators, thus decreasing the potential of crime scene/sample contamination.

![Figure 1](image_url)
Since the discovery of MALDI, many research groups have succeeded in measuring various proteins and large organic compounds by MALDI.\(^{14}\) MALDI has also been applied to DNA segments. Initially, success was limited to small DNA detection\(^{15}\) and gaining some understanding of the mechanism of the MALDI process.\(^{16}\) Then, Wu et al.\(^{17}\) discovered 3-hydroxypicolinic acid was a good matrix for mixed-base oligonucleotide and succeeded in detecting oligonucleotides of 67 bases. With the development of an instrument to give high ion energy and the use of new matrices, Tang et al.\(^{18}\) succeeded in using MALDI to detect single-stranded DNA (ssDNA) of 500 nucleotides and dsDNA of 500 bp. Berkenkamp et al.\(^{19}\) also reported the detection of 2000 bp DNAs with IR/MALDI. This clearly indicates that MALDI can be used for large DNA analysis. Recently, MALDI was also used for mutation detection for disease diagnosis caused by base deletion\(^{20}\) and point mutation\(^{21}\) for cystic fibrosis. Successful sequencing short DNAs by mass spectrometry has also reported.\(^{22–27}\) The success of mass spectrometry for DNA sizing and sequencing paved the way to use mass spectrometry for DNA typing for forensic applications. With mass spectrometry DNA profiling, there is a potential that the analysis time for each sample can be a few seconds instead of the hours needed by standard gel electrophoresis. Furthermore, no chemical or radioactive tagging or gel preparation is required.

2 MASS SPECTROMETRY DNA SIZING FOR FORENSIC APPLICATIONS

Each DNA typing involves (1) measurements of DNA fragments associated with genetic markers, (2) match determination for various genetic markers for different samples, and (3) statistical analysis for the type match to determine the possibility of an accidental match. As described above, all sequencing or size determination of DNA fragments for forensic applications has been performed with gel electrophoresis. Various approaches for DNA applications in the forensic community include the analysis of VNTR, STR, SNP and DNA sequencing. Laboratory protocol and standard procedures for data analysis were set up for forensic sample analysis. With the recent progress in development of mass spectrometry for DNA analysis, there is a good potential that mass spectrometry can be used for all the above applications. Since the use of mass spectrometry for DNA analysis is still in the early developmental stages, standard protocols for its use in forensic analysis have not been established. The potential applications of using mass spectrometry in DNA fingerprinting for forensic applications will be presented and discussed below.

2.1 Restriction Fragment Length Polymorphism and Variable Numbers of Tandem Repeats Analysis

DNA fingerprinting relies on the use of DNA markers. Among the most widely used DNA markers are RFLPs. RFLP analysis relies on differences that affect the position of restriction endonuclease recognition sites. Restriction endonucleases are enzymes which recognize and cut dsDNA at sequence specific recognition sites. Homologous DNA fragments from different individuals will contain different cut sites based on random mutations within the stretch of nucleotides. Consequently, fragments differing in length and number will be generated upon restriction digestion. These constitute RFLPs and, because they differ in size (length), the RFLP fragments can be readily separated by routine agarose electrophoresis.

When an individual’s entire genomic DNA is digested by a restriction endonuclease, hundreds to thousands of restriction fragments are produced. When digested genomic DNA is subjected to gel electrophoresis, individual bands are not discernible. In such a case, analysis is generally facilitated by the Southern blotting technique. In Southern blotting, digested DNA is separated by electrophoresis. The digested fragments are transferred to a nitrocellulose or nylon membrane through capillary action. The DNA binds to the membrane by electrostatic attraction. Labeled probes specific for the RFLP of interest are then hybridized to the DNA-containing membrane. A banding pattern can be visualized using autoradiography or chemical detection techniques. Each individual will exhibit a characteristic pattern. Several RFLPs must be used to statistically ensure an individual’s pattern is unique. The fact that RFLPs can occur anywhere in the genome and that there are potentially millions of RFLPs detectable with different probes makes RFLP analysis a tremendously powerful tool for forensic use.

A special class of RFLPs is based on DNA sequences that occur in tandem repeats. Tandem repeats arise when slippage mutation occurs during DNA replication. It has been observed that this type of mutation occurs frequently enough to generate significant variation over many generations. Polymorphism for these markers is so high in humans that only identical twins will have the same patterns. This factor makes the use of tandem repeats analysis extremely valuable to forensic scientists.

VNTR analysis has been used extensively in forensic applications. VNTRs consist of approximately 10 to 100 bp repeated several times in tandem. For example, a tandem repeat of the trinucleotide CTG would appear in the genome as CTGCTGCTGCTGCTGCTG. In this particular example this sequence has seven repeats. VNTRs are generally bordered by unique sequence DNA,
a characteristic that can be exploited by current technology. In VNTR analysis, genomic DNA is digested with a restriction endonuclease which does not contain a cut site within the tandem repeat sequence. Since the restriction enzyme cuts outside of the tandem repeat region, the tandem repeat is left intact. Tandem repeat fragments are separated by gel electrophoresis and analyzed with Southern blotting. The length of the tandem repeat will vary between individuals. Individuals can be homozygous or heterozygous for a particular VNTR. The large number of VNTR-containing loci creates millions of possible pattern combinations. If there are \( n \) loci, there should be \( n \) homozygotes and \( n(n-1)/2 \) heterozygotes. If \( m \) loci are analyzed, the number of possible genotypes is \( n(n+1)/2 \)^{\text{m}}. If \( n = 20 \) and \( m = 4 \), there are more than 1 billion genotypes. As a result, VNTR provides the forensic analyst with a powerful tool for inclusion and/or exclusion.

The need for Southern blotting can be eliminated if the VNTR region is selectively amplified with the PCR. PCR primers complementary to sequences flanking the tandem repeat region can be designed and used to amplify the tandem repeat region. The length of an individual’s tandem repeat can then be obtained by gel electrophoresis. It is PCR amplification of VNTRs that shows a lot of promise for MALDI detection. By using MALDI for RFLP detection, gel electrophoresis, Southern blotting and radioactive material or dye tagging can be eliminated.\(^{29,30}\) Figure 2 shows the mass spectra for restriction enzyme digested DNA samples. Hybridization probes can also be detected by MALDI.\(^{31}\) An example is shown in Figure 3. At present, detection of DNA of a size much larger than 500 bp is still not routine. It is preferred to use MALDI in RFLP for detection of small DNA fragments. A PCR process can be used to replicate a selected part of genomic DNAs. The PCR products can then be subjected to enzyme digestion to produce short DNA fragments for MALDI detection.

For VNTR analysis by measuring RFLP without the use of PCR, one major disadvantage is that the quantity of the DNA sample is so small that a long analysis time is required. One promising alternative is to amplify and measure loci containing STRs. There is a very large number of STRs distributed throughout the human genome. STR analysis can be used for as many loci as needed for reliable identification. PCR is nearly always used in STR analysis. Since PCR can amplify the selected DNA segments by more than six orders of magnitude, only a very small quantity of DNA sample is required. However, the disadvantage is that any procedure using PCR amplification is highly susceptible to contamination. Any trace foreign DNA contamination can be amplified and detected to potentially lead to a false conclusion. However, careful handling of DNA samples or applying quantitative PCR techniques can more or less resolve the concerns about DNA contamination. Since the analysis of STR is by measurement of the sizes of DNA products from the PCR process, the size of DNA fragments is often less than 300 bp and the quantity is often in the range of a few picomoles, which can be readily detected by MALDI.

A typical mass spectrum of a DNA sample amplified by PCR from a part of the vWFII gene is shown in Figure 4. Peaks for PCR products are clearly visible; a difference of 12 bases with three 4-base tandem repeats can clearly be observed. Both primary and doubly charged
Figure 4 Negative ion mass spectrum of PCR product: 166 and 178 bp in the intron 40 of human vWFII gene.

ion peaks are observed. The spectrum indicates that one chromosome in this region is 12bp longer than the same region in the other chromosomes. Thus, the result indicates that the sample is from a person with heterozygous vWFII. Several different genes were used for mass spectrometric detection; their repeat sequences and the range of their allele sizes are shown in Table 1. Take the F13B locus as an example. The maximum difference for the number of 4-base repeats is 5. There are 15 different genotypes for this locus. Since different people have different numbers of repeats in each of these genes, measurements of the number of repeats for several loci can be used for person identification. Examples of various mass spectra for different people for different loci are shown in Figure 5. The results were compared with results from gel electrophoresis, with good agreement. There are many tetranucleotide repeats which can be used for forensic identification. HUMTH01 is one that is often used for forensic application. Eight alleles were distinguished for identification purposes.

In addition to tetranucleotide repeats, trinucleotide repeats are common in many well-characterized genes which include Huntington’s disease, DRPLA (dental-toral–pallidolysian atrophy), Fragile X, etc. The numbers of the repeats for these genes are shown in Table 2. The use of MALDI for trinucleotide repeat detection in the DRPLA gene is shown in Figure 6. The number of repeats and the confirmation of homozygosity or heterozygosity can be readily obtained. With the combination of these loci, the number of possible genotypes can reach billions. Consequently, this technique proves to be useful for reliable identification. However, the use of genes associated with disease requires special caution regarding the use of random mating approximations for forensic application, since disease genes may have special distributions among different ethnic groups.

2.3 Single-nucleotide Polymorphism

There are several types of DNA sequence variation, which include deletion, insertion, difference in number of repeats such as STR, and single bp differences. The single base difference is the most common. It was estimated that two random human homologous chromosomes differ at a frequency of about 1 in 300–1000 bases. This single bp difference is often referred to as a SNP. There are several million SNPs in the human genome. The predominance of SNPs and the much lower mutation rate makes SNP analysis extremely valuable for both forensic and medical applications.

Allele-specific hybridization is often used for SNP detection. It often requires incubation, washing and careful control of temperature and salt concentration. However, discrimination often can be difficult due to imperfect complement hybridization. Another approach is to use allele-specific polymerase chain reaction (ASPCR). Mass spectrometry can be used for the analysis of PCR products. ASPCR/MALDI has been pursued for a simulated fragment of the p53 gene. The sequence of the template and the primers used are:

a Sequence located in intron 40 with different primers to generate different sizes of repeat-containing fragments.
Upstream and downstream primers are overlapped at the base, which may be the site for base difference. If the template is normal, PCR will proceed. The size of amplified DNA product is 38 bp. The experimental result is shown in Figure 7. For a template with the base difference, no PCR products are expected. Results for this case are shown in Figure 8. This approach has also been applied to G551 in the cystic fibrosis transmembrane conductance regulator (CFTR) gene with human samples. Since the lengths of primers can be varied, multiplexing can be applied to monitor several SNP in a single sample.

Another approach to the use of MALDI for SNP detection is to hybridize a primer adjacent to the

polymorphic locus and extend it by a single base by dideoxynucleotide addition. Mass spectrometry can be used to accurately measure the mass of the extension product in order to identify the base. For homozygotes, one peak will be observed. However, two peaks should be observed for a heterozygote. Since different lengths of primers can be used for extension, it is possible to achieve a high throughput.

2.4 Gender Determination

Sex determination is often important for identifying suspects and victims. A reliable gender test is PCR amplification of a segment of the X–Y homologous gene amelogenin. A single pair of primers spanning part of the first intron generates 106 bp and 112 bp PCR products from the X and Y chromosomes respectively. MALDI can be subsequently used for the measurements of PCR products. Recently, it was found that the deletion of the Y-encoded gene occurs in a small percentage of Y chromosomes. Thus, it is more reliable to test both amelogenin and the male sex determining gene SRY for gender determination. Co-amplifications of genomic templates are listed in Table 3. Male DNA generates three products of 93 bp (SRY), 106 bp (amelogenin in the X chromosome) and 112 bp (amelogenin in the Y chromosome). Co-amplification of female DNA

3 DNA SEQUENCING BY MASS SPECTROMETRY FOR FORENSIC APPLICATIONS

It is obvious that a complete sequencing of the human genome for each individual should reach the highest reliability for person identification. The sequencing of a selected DNA fragment should also be more reliable than just measuring STR or SNP. However, sequencing with gel electrophoresis is much more time-consuming and labor-intensive than just measuring the size of DNA. Furthermore, the sequencing process often needs the use of polyacrylamide gel instead of agarose as the gel matrix. Acrylamide requires more careful handling and generally takes longer to run. DNA sequencing by mass spectrometry is orders of magnitude faster than gels and can be done directly, without generating DNA ladders. Thus, direct sequencing with mass spectrometry can be
just as fast as measuring the size of DNA fragments alone. At the present time, the low mass resolution of MALDI for DNA limits the size of DNA fragments which can be sequenced to approximately 200 bp. However, it is not always necessary to sequence a long piece of DNA for forensic application because a polymorphic profile is already known. Thus, DNA sequencing by mass spectrometry can become a valuable tool for forensic application in the future.

3.1 DNA Sequencing by Mass Spectrometry with DNA Ladders

DNA sequencing has been broadly used for biomedical research and clinical applications over the past two decades. Rapid and reliable DNA sequencing can also be very valuable for forensic applications. With the conventional sequencing approach, different sizes of DNA ladders, which are produced by either Sanger’s enzymatic method or Maxam–Gilbert’s chemical cleavage method, are separated by gel electrophoresis to achieve sequencing. With MALDI for sequencing, the speed can be significantly faster than gel electrophoresis. In addition, MALDI sequencing does not require labeling for identification, which saves both time and cost.

During the past few years, mass spectrometry for sequencing short DNA fragments has been pursued. In 1995, Shaler et al. reported the first sequencing of a 45-mer ssDNA using MALDI/TOF with enzymatic preparation of DNA ladders. Recently, Roskey et al. reported the results of sequencing a synthetic ssDNA template of 50 nucleotides. Koster et al. also succeeded in sequencing synthetic ssDNA of 39 nucleotides using streptavidin-coated magnetic beads for purification of DNA ladders. Mouradian et al. reported MALDI analysis of sequencing reactions from bacteriophage M13 and succeeded in determining the sequence for samples up to 35 bases in length. A complete sequencing effort for a ssDNA with 50 bases was demonstrated with no false stops, no serious fragmentation, and no unidentified peaks by Taranenko et al. Recently, sequencing ssDNA higher than 100 nucleotides by using cycle sequencing to produce DNA ladders was reported. Figure 11 shows the negative-ion mass spectra of DNA ladders from A, C, G and T reactions using dsDNA 130 bp as the template with reverse primer. Forward primers were also used for sequencing, with results similar to the data shown in Figure 11. Since sequencing by using both forward and backward primers can reach 120 mer, complete sequencing of 200 bp DNA can be achieved. Figure 12 illustrates the idea of combining the spectra from forward and backward primers to sequence dsDNA with a 200 bp template. Owing to the measurement of mass to identify the size of DNAs, there is no concern about a missing band, which can occur in the gel electrophoresis method. Thus, redundant sequencing can possibly be eliminated with MALDI DNA sequencing.

At present, automatic gel sequences can read up to 1000 bp, but most routine sequencing ranges from 300 to 500 bases. With MALDI now able to sequence 200 bp, mass spectrometry is emerging as a useful tool for DNA sequencing for forensic analysis, since most STR and SNP analysis does not need sequencing longer than 200 bp. Mass spectrometry sequence detection utilizes inexpensive unlabeled primers and also has the additional advantages of higher sequencing speed and the ability to obtain sequence information close to the primer.
3.2 Direct Sequencing

When using mass spectrometry for sequencing DNA with ladders, the time needed for a TOF mass spectrometer to separate and detect various ladders only takes a few seconds. However, the time needed to prepare DNA ladders needs many minutes to hours. Thus, the ideal sequencing method would be if mass spectrometry could be used to do direct DNA sequencing without the need to produce DNA ladders with chemical or enzymatic methods. This also implies that DNA ladders need to be produced during the laser ablation process.

Direct DNA sequencing can be easily understood by using Figures 13 and 14. Assuming the selective cleavage produced during the laser ablation process. This also implies that DNA ladders need to be used to do direct DNA sequencing without the need sequencing method would be if mass spectrometry could be used to do direct DNA sequencing without the need to produce DNA ladders with chemical or enzymatic methods. This also implies that DNA ladders need to be produced during the laser ablation process.

Figure 15 The mass spectrum of MALDI, with selective fragmentation for direct sequencing of a 35-mer oligonucleotide, 5′-GCGTGATGGAATCGATGACGTGCGATGTGGTT-3′. Simulated spectra are shown as the lower traces in (a) and (b). The high-intensity series in the simulated spectra is the 5′-termini and 3′-cleavage series and the lower-intensity series is the 3′-termini and 3′-cleavage series. A mixture of 2,4,6-trihydroxyacetophenone (1.5 × 10⁻³ mol) was used as a matrix. The quantity of 35 nucleotide DNA was 100 pmol. (a) and (b) are the low- and high-mass regions, respectively.

| ion peaks needs to be better than 1 in 2000, since the mass difference between A and T is only 9 Da. When a DNA segment is longer than 100-mer, the effect of the abundance of the 13C isotope makes the distinction between A and T extremely difficult. However, direct sequencing can still be applied to certain SNP samples when the sequence and the positions of possible variants are known and the segments to be sequenced can be short.

4 CONCLUSION

Mass spectrometry for DNA fingerprinting by VNTR, STR, SNP and sequence analysis is emerging as a new and powerful tool for forensic applications. Its special advantages include its much faster speed than conventional gel methods and its ability for detection without radioactive or dye tagging. In the near future, special effort should be put into improving mass resolution so that longer DNA samples can be used for STR, VNTR and SNP analysis. Better mass resolution can also extend SNP analysis and DNA sequencing to longer DNA segments for broader forensic applications. Robotic automation for sample preparation and analysis also needs to be developed to achieve high throughput analysis to obtain a database for future searches for suspects. Since the transport of DNA samples can sometimes lead to the contamination or deterioration of samples, it is desirable to have a transportable device for DNA analysis. Mass spectrometry for DNA analysis can be more convenient than gel electrophoresis to adapt for in situ and real time analysis as well as for automation for high throughput analysis.
